My position, as well as that of Daum and Smith,[101] is that the argument for performing elective tracheostomy or, preferably, intubation in all children with supraglottitis is compelling, and the procedure should be performed immediately after the diagnosis is established. Whether this "stimulus-response" approach is necessary for adults with epiglottitis is controversial.† MayoSmith and associates[274] compared selected clinical features in adults with epiglottitis at the time of diagnosis who died or who received an artificial airway with those of adults who recovered without airway intervention. Few differences emerged. Patients who died or who were managed with airway intervention had respiratory distress and bacteremia more often than did those who recovered without airway intervention. Obviously, the presence of bacteremia was not known on presentation. Moreover, the mortality rate among all adults managed expectantly was 4.6 percent, a figure comparable to the mortality rate (6.1%) of children in a series reported before recommendations were made for routine securing of the airway at diagnosis.[67,274] The preponderance of evidence until very recently has suggested that securing the airway in all adults with supraglottitis by nasotracheal intubation should reduce mortality rates.* However, Frantz and associates[144] reported an analysis of 129 cases of acute epiglottitis in adults in which no deaths occurred in the cohort and 85 percent of these patients were managed without airway intervention.

In the large series reported by Berger and colleagues[33] involving 118 cases, 19 had airways established on admission (16 endotracheal intubation, 2 tracheotomy, 1 cricothyrotomy), and 6 other patients subsequently required either endotracheal intubation or tracheotomy. The remaining 93 patients were managed successfully without the need for airway intervention. Fifty-eight of the patients were treated with intravenous corticosteroids in addition to antibiotics, and these patients tended to have more prolonged hospital stays than those who did not receive steroids (5.7 ± 4.1 days vs. 4.7 ± 4.3 days; $p = .2$).

To aid in intubation and reduce long-term sequelae, most investigators have advocated use of a nasotracheal tube 0.5 to 1.0 mm smaller than that predicted by the patient's age.[179,285,356] Published criteria for extubation (summarized in reference 14) include those based on duration of therapy and those based on daily examination of the epiglottis and supraglottic structures by direct laryngoscopy[104] or fiberoptic bronchoscopy.[307,425]

Long-term complications of nasotracheal intubation are rare. Thirty-three children with epiglottitis who were managed with nasotracheal intubation (mean duration of intubation, 55 hours) were evaluated 1 to 8 years later. By history and measurement of peak expiratory flow rates, no complications were found.[356] Although additional long-term data are necessary to ensure absence of residua, elective nasotracheal intubation appears to be the procedure of choice.

Several reports documented the recognition of idiopathic pulmonary edema before[251] or, more commonly, after† insertion of an endotracheal tube to relieve laryngeal obstruction caused by epiglottitis. One hypothesis to explain this phenomenon is that airway obstruction produces markedly negative intrapleural pressure with increased venous return to the right side of the heart, with decreased left ventricular output and increased pulmonary blood volume.[248] These changes increase the pulmonary microvascular pressure and produce pulmonary hyperemia and edema. Endotoxemia may play a role in altering vascular permeability, but it is not necessary for recognition of this complication of airway obstruction because abrupt onset of pulmonary edema was described when airway obstruction caused by croup, foreign body, and malignant neoplasm was relieved acutely.[63] The frequency of pulmonary edema as a complication of intubation in supraglottitis was approximately 9 percent,[379] and it has occurred in an adult.[338] Continuous positive airway pressure in all intubated patients with epiglottitis probably will provide prophylaxis against this complication,[115,147] but controlled data are lacking.

Antibiotics

The mainstay of antibiotic therapy for acute epiglottitis in the recent past has been ceftriaxone 50 to 100 mg/kg/day given every 12 hours intravenously or cefotaxime 100 to 200 mg/kg/day given every 6 hours intravenously, because virtually all cases in both children and adults were caused by *H. influenzae* type b. However, in the present conjugate vaccine era, the incidence of all invasive *H. influenzae* type b disease has decreased dramatically. Therefore, in children previously vaccinated, the cause is likely to be another organism. Culture results today have added significance because one possible cause that would require a change in therapy is *S. aureus*.

No controlled data exist about the duration of antimicrobial administration, but a course of 7 to 10 days seems appropriate. In the event that group A streptococci are isolated from the airway, penicillin is the drug of choice. A first-generation semisynthetic penicillinase-resistant penicillin or vancomycin (if MRSA is suspected) should be used for *S. aureus*.

Other Supportive Measures

Expert respiratory nursing care is essential. Inadvertent extubation must be avoided, particularly in the first 24 hours. Judicious use of sedatives that do not appreciably depress respiration may be appropriate.

PROGNOSIS

The prognosis of acute laryngotracheitis has improved markedly during the last 55 years. Today, a child with croup only rarely requires a mechanical airway, and virtually all deaths should be preventable. The child should be observed for the following complications: hypoxemia and cardiorespiratory failure, pulmonary edema, pneumothorax and pneumomediastinum, mechanical problems caused by tracheotomies and nasotracheal tubes, and secondary bacterial infections. Children with a history of croup have a higher prevalence of increased bronchial reactivity than children without such history.[170,265,441]

The prognosis in epiglottitis after the successful establishment of an airway and the administration of specific antimicrobial agents is generally good.

Extraepiglottic complications are not common occurrences in children with acute epiglottitis. In a study involving 72 children with epiglottitis, investigators noted that 25 percent had pneumonia, 25 percent had cervical adenitis, 8 percent had tonsillitis, and 5 percent had otitis media.[289] The other common invasive manifestations of *H. influenzae* type b infections (meningitis, arthritis, and cellulitis) rarely are found in conjunction with epiglottitis.[289,355]

PREVENTION OF CROUP

At present, acute laryngotracheitis is not preventable. The widespread use of influenza vaccines could reduce the incidence of croup caused by influenza A and B viruses.

Prevention of Epiglottitis Caused by *Haemophilus influenzae* Type b

The universal use of *H. influenzae* type b vaccine in infancy with an additional dose in the second year of life has had a profound effect on the occurrence of invasive *H. influenzae* type b diseases.

In the pre–conjugate vaccine era, household contacts of patients with *H. influenzae* type b infection were at increased risk for acquiring the infection.[165] Whether an increased risk occurred in daycare contacts was unresolved.[103] Although contacts of patients with *H. influenzae* type b epiglottitis younger than 5 years of age are colonized less frequently than contacts of patients with other *H. influenzae* type b invasive infections,[102] secondary disease was described in household contacts when an index patient had epiglottitis.[2,160,161,415] Secondary *H. influenzae* type b epiglottitis was described in a child[2] and two adults who were household contacts of a patient with *H. influenzae* type b meningitis.[160,161] *H. influenzae* type b epiglottitis occurred in two siblings who presented with the condition within 1 day.[174]

Rifampin prophylaxis with 20 mg/kg/day (600 mg/dose maximum) for 4 days, is recommended for all unvaccinated members of a patient's contact group when the index patient has *H. influenzae* type b epiglottitis and at least one contact in the group is 4 years of age or younger.[8,69]

The recognition that adults occasionally may acquire secondary infection, particularly epiglottitis, on exposure to children with invasive *H. influenzae* type b infection prompted some experts to extend prophylaxis to all of a patient's contact groups, regardless of the presence of one or more contacts who are 4 years of age or younger. All experts, however, recommended that adults and older children be made aware of the signs and symptoms of *H. influenzae* type b disease, particularly when the patient's contact group would not receive prophylaxis under current guidelines.

SECTION **II**

LOWER RESPIRATORY TRACT INFECTIONS

CHAPTER 19

Acute Bronchitis

James D. Cherry

Bronchitis is a common diagnosis in pediatric practice, although little unanimity exists among physicians regarding its exact clinical constellation and in the true pathologic sense it probably never occurs as an isolated entity. Acute bronchitis is a febrile illness with cough, rhonchi, and referred breath sounds.[13] Asthmatic bronchitis (infectious asthma), similar to acute bronchitis but with associated wheezing and expiratory distress, is discussed in Chapter 21. On pathologic examination, the clinical illness of acute bronchitis reflects acute inflammatory disease of the larger air passages, including the trachea and the large and medium-sized bronchi.[22]

ETIOLOGY

Table 19-1 lists various infectious agents associated with acute bronchitis. Infections with adenoviruses, influenza viruses, parainfluenza viruses, respiratory syncytial virus, and *Mycoplasma pneumoniae* account for most cases of acute bronchitis in children. These agents, plus many rhinoviruses, a few enteroviruses, and perhaps human metapneumovirus, human bocavirus, and the newer human coronaviruses, account for virtually all cases in the United States today.

Of the adenoviruses, type 7 has been associated most commonly with acute bronchitis in children. In military recruits, including adolescents, adenovirus types 4 and 7 cause epidemic acute respiratory disease, in which bronchitis is a usual occurrence.[19,62]

Influenza A virus infection is a common cause of severe acute bronchitis, particularly at the time of an antigenic shift of influenza A virus subtype and pandemic disease. Acute bronchitis caused by influenza A virus also is a regular occurrence between pandemics in new susceptible individuals (young children) in the population. Influenza B virus also is an important cause of bronchitis, and it was a more common causative agent than was influenza A virus in one large longitudinal study.[12]

All cases of measles involve the bronchi, but measles has been an uncommon occurrence since the advent of widespread use of vaccines. Of the parainfluenza viruses, type 3 is associated most commonly with acute bronchitis. Respiratory syncytial virus is a common cause of acute bronchitis, particularly in very young children. The more recently identified human metapneumovirus and human bocavirus are also causes of acute bronchitis.[16,54,60,69,70]

Of the bacterial agents listed in Table 19-1, only *Haemophilus influenzae* clearly can be incriminated. *Bordetella pertussis* infection involves the trachea and bronchi, but fever is an uncommon event and the illness is outside the definition of acute bronchitis. When sought, *M. pneumoniae* is a common cause of bronchitis. *Chlamydia pneumoniae* has been found to be the cause of bronchitis in adolescents and young adults.[29]

EPIDEMIOLOGY

The epidemiology of the common viruses associated with bronchitis is presented in Section XVII. Chapman and associates[12] published the results of a study of acute bronchitis in a single private group pediatric practice in Chapel Hill, North Carolina. The study occurred during a 104-month period, during which 5489 episodes of lower respiratory tract illness occurred. Of these illnesses, 40.1 percent were acute bronchitis. The bronchitis attack rate was highest in children in the second year of life (6.71%), and then it decreased gradually to approximately 2 percent in teenagers. In contrast to the age-specific attack rates, the ratio of bronchitis cases to all lower respiratory illness cases increased with age. In the first year of life, the ratio was 0.29; in children 12 years old or older, it was 0.69.

During the first 6 years of life, respiratory syncytial virus and parainfluenza virus type 3 were the most common etiologic agents noted in the Chapel Hill study. During the first 2 years of life, adenoviruses also commonly were associated with bronchitis. In patients older than 6 years, *M. pneumoniae* and influenza A and B viruses were the most common etiologic agents. In a study of cough illnesses of 6 days' duration or longer in university students, investigators found that 15 of 31 students with laboratory evidence of *Bordetella* spp. infection were considered by their primary care providers to have bronchitis.[42]

The incidence of acute bronchitis peaks in the winter months, declines to midsummer, and increases again through the fall. Attack rates generally are higher in boys than in girls.[12,36,63] A sex difference is most pronounced during the first 6 years of life.

PATHOPHYSIOLOGY AND PATHOLOGY

Because acute bronchitis is an illness characterized by clinical features and one not usually associated with death, knowledge of its pathophysiology and pathology

TABLE 19-1 **Infectious Agents Associated with Acute Bronchitis**

*+++, very common; ++, common; +, rare; –, of questionable etiologic significance

is meager. The general pathophysiology of human infections with viruses and *M. pneumoniae* that cause acute bronchitis is presented more completely in the sections of this book related to the individual infectious agents.

In virtually all cases of acute bronchitis, evidence of upper respiratory tract viral infection (pharyngitis, rhinitis) also is present. Tracheal and bronchial infection apparently is the result of distal spread. In bronchitis, the clinical features result from damage to the ciliated epithelium of the lower trachea and the large and medium-sized bronchi.[22] Although the cytopathologies of the various infectious agents is different,[71] the resulting obstruction of the air passages leads to similar symptoms. The duration of symptoms depends to some extent on the specific initial infectious agent and, in cases of prolonged illness, on secondary bacterial infection.

In acute bronchitis, the larynx and subglottic trachea are not involved prominently. Conversely, today, bronchial involvement is seen only occasionally in croup.

CLINICAL PRESENTATION

Initial manifestations of acute bronchitis occur in the upper respiratory tract and, depending on the etiologic agent, are predominantly nasal, as in the common cold, or show additional objective evidence of pharyngitis, as in nasopharyngitis. Fever usually is present, and temperatures vary from 37.8°C to 39°C (100°F to 102.2°F) on most occasions. Cough is always present, and its onset can be insidious or abrupt. Initially, the cough is dry and harsh and often brassy in younger children. As the illness progresses, the cough becomes looser. In older children, purulent sputum is raised and expectorated. In younger children, the swallowing of often tenacious sputum frequently leads to gagging and vomiting. Older children may complain of chest pain resulting from coughing.

On initial physical examination, a variable degree of rhinitis usually is present; many patients have diffuse pharyngeal erythema. As the disease progresses, these upper

respiratory tract signs generally decrease. Examination of the chest reveals rhonchi and referred breath sounds. Coarse, changing rales are noted frequently.

In the usual case of acute bronchitis, the illness can be separated into three phases: (1) a 1- to 2-day prodromal period when fever and upper respiratory tract symptoms predominate, (2) a 4- to 6-day period of marked tracheobronchial symptoms with some fever and general discomfort, and (3) a recovery period that may last 1 or 2 weeks and is characterized by cough and expectoration. Occasionally, the recovery period is particularly distressing and is associated with a low-grade fever, suggesting secondary bacterial infection. Bronchitis caused by *C. pneumoniae* often is insidious in onset and frequently associated with or preceded by pharyngitis.[29,37] Illness persists for several weeks but responds to appropriate antibiotic therapy.

Laboratory study in acute bronchitis is of limited use. Children in whom throat cultures reveal pathogenic bacteria in predominant growth tend to have more severe illness than do children with only viral infections.[14,44] The white blood cell count usually is greater than 10,000 cells/mm^3, and approximately one third of the cases have a predominance of neutrophils.[44] The chest radiograph is normal unless associated pulmonary involvement is present.

DIFFERENTIAL DIAGNOSIS AND SPECIFIC DIAGNOSIS

Because acute bronchitis is a clinical entity caused by multiple etiologic agents, the most difficult differential aspect of diagnosis is the selection of the specific infectious cause. Also important is the separation of acute, self-limited bronchitis from chronic, more serious problems, such as cystic fibrosis, allergic respiratory disease, and sinusitis.

An epidemiologic history frequently can help in assigning a particular virus, *M. pneumoniae*, *C. pneumoniae*, or *B. pertussis*, as the presumptive etiologic agent. If epidemic bronchiolitis is occurring in the community, respiratory syncytial virus would be a likely cause. Similarly, predictions of causation by influenza virus, parainfluenza virus, adenoviruses, *M. pneumoniae*, *C. pneumoniae*, or *B. pertussis* can be made through clinical epidemiologic observations. Specific etiologic diagnosis can be established through the isolation of an organism or its identification by a direct antigen test or polymerase chain reaction from the nasopharyngeal secretions. Serologic study on paired sera may be useful for the diagnosis of *M. pneumoniae*, *C. pneumoniae*, and *B. pertussis*. Single serum IgM studies are useful in the diagnosis of *M. pneumoniae* and *C. pneumoniae*. Single serum study is also useful in the diagnosis of *B. pertussis* infection; specifically the demonstration of significant immunoglobulin (Ig)G or IgA values to pertussis toxin.

Children with protracted illnesses or febrile exacerbations should be examined by culture, radiograph, and perhaps further imaging studies for secondary bacterial infection of the tracheobronchial tree or the lungs or both. Children with chronic recurrent illnesses should be tested for cystic fibrosis, allergic conditions, and anatomic problems, such as gastroesophageal reflux and tracheoesophageal fistula.

TREATMENT

Treatment of acute bronchitis is distinguished more by what *not* to do than by specific modalities. In most mild cases, no specific therapy is indicated.

For children who feel miserable during the initial phases of acute bronchitis, analgesic therapy may be useful. Formerly, aspirin was the recommended analgesic. Because aspirin is an etiologic factor in influenza-associated Reye syndrome and because differentiating influenza viral infections from other respiratory viral infections is difficult, it is prudent to use acetaminophen rather than aspirin. The dose per single administration of acetaminophen by year of age is as follows: younger than 1 year, 60 mg; 1 to 3 years, 60 to 120 mg; 3 to 6 years, 120 mg; 6 to 12 years, 150 to 300 mg; older than 12 years, 325 to 650 mg. Administration may be repeated three or four times daily in young children and every 4 hours in older children. Acetaminophen rarely should be given to infants younger than 6 months of age.

As a result of widespread advertising, a common practice of individuals with acute bronchitis is to use an array of cold remedies, which contain various combinations of antihistamines, decongestants, and antitussives. None has been shown to be useful in acute bronchitis, and in certain stages of illness, they may aggravate the recovery process.

Intake of fluids should be encouraged to prevent overall dehydration and decrease the viscosity of new secretions. Use of mist therapy also may help in thinning the exudate-containing respiratory secretions.[21,47]

In severe cases of acute bronchitis, treatment with specific antiviral agents should be considered. When influenza A virus is the likely etiologic agent, zanamivir or oseltamivir therapy may be beneficial.[8]

As noted in Table 19-1, most cases of acute bronchitis are caused by viruses, so antibiotic therapy would not be indicated.[45,67] In cases in which fever returns or no trend toward recovery is seen by the seventh day of illness, the possibility of a secondary bacterial infection should be considered. The association of sinusitis or a throat culture with predominant growth of a respiratory pathogen (*Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Moraxella catarrhalis*, *H. influenzae*) is an indication for therapy. Infection with *M. pneumoniae* also should be treated, but in contrast to treatment of pneumonia, the therapy usually does not show an impressive response. Bronchitis caused by *C. pneumoniae* should be treated with erythromycin or another macrolide.[29,46]

PROGNOSIS

The prognosis in acute bronchitis usually is excellent. Although the duration of cough can be disturbing to the parent and the child, full recovery is the rule. Several studies suggest that lower respiratory tract illness in the first few years of life may be associated with persistent

respiratory symptoms and with abnormalities in lung function in later life.[6,17,40,41] Although none of these studies has followed children with acute bronchitis specifically, the findings in other illnesses (bronchiolitis and croup) indicate a need to observe children with episodes of acute bronchitis carefully, as well.

PREVENTION

At present, no practical method of prevention of acute bronchitis in children exists. Because most cases result from infections with common respiratory viruses, the development of vaccines could be expected to be helpful.

CHAPTER 20

Chronic Bronchitis

I. Celine Hanson • William T. Shearer

Chronic bronchitis is a serious and costly health problem in adults.[14] The World Health Organization estimates 23.6 million adults have chronic obstructive pulmonary disease, representing more than 15 percent of the adult population, and many of these cases meet the definition for chronic bronchitis.[14] A diagnosis of chronic bronchitis without chronic obstructive pulmonary disease was present in 3.5 percent of 10,000 adults in a French study cohort.[9] In the adult literature, the accepted definition of chronic bronchitis includes daily excessive production of sputum with manifestation of cough present on most days for 3 months in a year for not less than 2 successive years.[43]

For most pediatricians, the clinical entity of chronic bronchitis is ill-defined. Chronic cough complex can be associated with other, more common respiratory or cardiac diseases that must be excluded before a diagnosis of chronic bronchitis is considered.[6] Chronic bronchitis usually is described in the literature as chronic productive cough and is synonymous with asthmatic bronchitis.[39] The lack of uniform or standardized definitions of pediatric chronic bronchitis leads to wide discrepancies in reported childhood prevalence (Table 20-1). In affected patients, causal relationships and acute exacerbations have been linked to exposure to a noxious inhaled agent (e.g., environmental or industrial pollution, cigarette smoke), specific host factors (e.g., genetic predisposition), and infectious respiratory pathogens. The pathology of the disease entity is unclear. Bronchoscopy of pediatric patients with chronic bronchitis has revealed findings similar to those noted in children with asthma (granulocyte and mononuclear cell predominance at lavage and biopsy), which reflects the inclusion of asthma in the spectrum of the chronic bronchitis complex.[20,39]

DIFFERENTIAL DIAGNOSIS

Because chronic bronchitis is accepted by most physicians as being a complex of symptoms characterized by persistent cough with or without wheezing, it is imperative that the physician evaluate the patient for diseases that include chronic bronchitis within their spectrum of signs and symptoms. Figure 20-1 includes disorders that have clinical manifestations of chronic cough for longer than 3 months and provides guidelines for diagnostic

evaluation of children with chronic cough.[12] Many of these disorders are accompanied with abnormal chest radiographs, including evidence of bronchiectasis.

Heading the differential list is asthma, defined as reversible obstructive airways disease with a significant inflammatory component leading to increased edema and production of mucus. In the United States in 2006, more than 6.8 million children younger than 18 years had asthma and 4.1 million reported an asthma attack in that year.[21] Asthma can be distinguished from chronic bronchitis by pulmonary function evaluation documenting reversal of airway obstruction after delivery of pulmonary bronchodilators. Recurrent episodes of acute bronchitis often can be interpreted as chronic bronchitis, although the intermittent nature of these episodes and absence of a persistent cough usually distinguish this group of patients clinically.[2]

Specific viral infections (e.g., rhinovirus, respiratory syncytial virus) in children with or without allergic rhinitis may provoke airway hyperreactivity and late onset

of asthma, which may be confused symptomatically with chronic bronchitis.[13] Persistent lower respiratory tract infections (i.e., *Chlamydia* spp., pertussis, *Mycoplasma* spp., and *Mycobacterium* spp.) frequently manifest with the complex of symptoms described or chronic wet cough and are evaluated best with chest radiographs in a search for enlarged hilar nodes or interstitial lung infiltrates.[44] Respiratory tract secretions for appropriate bacterial and viral culture and serum for determinations of antibacterial antibodies should be obtained. In the case of tuberculosis, a delayed hypersensitivity skin test for *Mycobacterium tuberculosis* antigen should be applied.

Cystic fibrosis is a recessively inherited illness occurring in approximately 1 in 3700 live births, with clinical manifestations of failure to thrive, steatorrhea, nasal polyps, and recurrent lower respiratory tract symptoms. The disorder is associated with mutation of the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene.[32] Cystic fibrosis can be diagnosed by newborn screening methodologies, including identifying typical *CFTR* gene mutation patterns in DNA extracted from collected blood specimens on Guthrie cards at or after birth or by detecting abnormally elevated chloride levels (>60 mEq/L) as measured by the sweat iontophoresis test.[35] In clinical practice, one or both modalities may be used for establishing the diagnosis, especially for patients with genetic variations of the *CFTR* gene not typical of the classic cystic fibrosis phenotype or for patients with uninterpretable sweat test outcomes.

Primary ciliary dyskinesia encompasses the immotile cilia disorders and Kartagener syndrome (rhinosinusitis, bronchitis or bronchiectasis, situs inversus) and affects 1 in 16,000 births in the United States.[1] Primary ciliary dyskinesia typically is inherited as an autosomal recessive disorder and is associated with defects in mucociliary transport in the respiratory tree. The symptom complex also has been associated with polycystic kidneys, hepatic disease, and central nervous system symptoms. Screening tests for primary ciliary dyskinesia include nasal nitric oxide and in vivo tests of ciliary motility, but these tests are not universally available, and standardization is problematic.[23] Genetic testing is commercially available and can detect disease-causing mutations in autonomic genes coding for outer dynein arms (present in 60% of affected individuals), radial spoke, and cytoplasm proteins involved in dynein arm assembly.[24]

The primary immune disorders associated most frequently with recurrent sinopulmonary infections include selective immunoglobulin (Ig)A deficiency, functional antibody deficiencies, hypogammaglobulinemia, and ataxia telangiectasia.[22] Selective IgA deficiency is the primary immune disorder encountered most commonly, with an incidence of 1/500. It may be asymptomatic or accompanied by a propensity for atopy and an increase in associated autoimmune disease (most often rheumatoid arthritis and systemic lupus erythematosus). The diagnosis is made readily by evaluation of quantitative serum immunoglobulins defining IgA levels of less than 10 mg/dL. IgA deficiency may be associated with IgG subclass deficiencies (IgG2 deficiency was identified in 85% in a series of >150) with or without clinical symptoms. Functional antibody deficiencies have been detected and include inability to respond serologically to vaccination with polysaccharide antigens such as *Streptococcus pneumoniae* or *Haemophilus influenzae* type b.[7]

Patients with hypogammaglobulinemia represent a diverse group having primary immune disorders that include X-linked agammaglobulinemia, common variable immune deficiency (CVID), and hyper-IgM syndrome. X-linked agammaglobulinemia typically affects boys, who experience recurrent sinopulmonary infections with onset occurring postnatally as maternal antibody wanes. X-linked agammaglobulinemia is associated with deficiency of a B-cell maturation enzyme, Bruton tyrosine kinase, and is characterized by the absence of circulating mature B lymphocytes. CVID is a disorder of young adults with immune findings of agammaglobulinemia and variable T-cell defects. Clinical presentation includes lower respiratory tract and sinus disease. Inherited CVID disorders have been described and include defects in inducible T-cell costimulator gene and transmembrane activator and calcium-modulator and cyclophilin ligand interactor (TACI).[22] Patients with TACI defect and CVID may lack circulating mature B lymphocytes. More often, patients with CVID normally express B-cell markers on circulating lymphocytes. Hyper-IgM syndrome is a rare disorder associated with elevated IgM and low IgG and IgA and recurrent infections, including sinopulmonary and hepatic infections. Different gene defects have been identified in patients with hyper-IgM syndrome; patients with defects in nucleotide-modifying enzymes located only in B cells have no associated T-cell defect.

Patients with ataxia telangiectasia have depressed serum IgA concentrations and marked dysfunction of the swallowing mechanism, leading to recurrent lower respiratory tract infections probably secondary to recurrent aspiration. These patients are identified by telangiectasias of the skin and conjunctivae in association with aberrant and progressively deteriorating neurologic symptoms and immunodeficiency (depressed IgA and IgE and aberrant T-cell–mediated immunity). Some patients have depressed IgG subclasses (IgG2, IgG4) as well. The gene mutation in ataxia telangiectasia has been identified as disruption of the ataxia telangiectasia molecules responsible for detection and implementation of DNA repair dependent on phosphatidylinositol-3-kinase signal transduction pathways.

Primary immune disorders with hypogammaglobulinemia can be diagnosed through evaluation of serum immunoglobulin levels. Further characterization includes assessment of antibody production after vaccine or neoantigen challenge, evaluation of circulating lymphocyte cell surface markers, and in vitro proliferative responses to plant lectins or specific antigens. Evaluation of associated gene defects is important for determining corrective interventions (e.g., transplantation, gene therapy) and genetic counseling.

Graft-versus-host disease affecting the lungs has been described in immunocompromised patients after they have undergone bone marrow transplantation. The lesion is caused by chronic pulmonary lymphocytic infiltrates and pulmonary fibrosis mimicking the symptom complex of chronic bronchitis and often is indistinguishable

radiographically or clinically from infections that characteristically are pathogenic (i.e., *Pneumocystis jiroveci*, *Candida albicans*, *Aspergillus* spp.).

Secondary immune disorders (prematurity and pediatric human immunodeficiency virus [HIV] infection) also may be associated with significant sinopulmonary infections. Premature infants with attendant severe respiratory distress syndrome requiring positive-pressure ventilation may develop bronchopulmonary dysplasia. Diagnostic criteria include hypoxia requiring oxygen supplementation, characteristic diffuse interstitial markings on chest radiograph, and clinical signs of pulmonary disease (i.e., tachypnea, intercostal retractions). In one series, more than 60 percent of surviving children with bronchopulmonary dysplasia were documented to have significant pulmonary disease and associated morbidity (i.e., increased hospitalizations).[28] Continued improved care for premature infants and resultant decreased incidence of mortality may increase the population of infants with bronchopulmonary dysplasia.

Pediatric HIV infection has declined and is documented to affect approximately 2 percent of infants born to HIV-infected mothers in the United States and Puerto Rico.[41] This reduced infection rate can be attributed to (1) availability and use of highly active antiretroviral therapy (HAART) in pregnant women and their newborn infants, (2) U.S. practices that minimize exposure to breast milk, and (3) obstetric practices that minimize exposure to infected blood products (cesarean delivery and practices that decrease time from membrane rupture to delivery). Continued maternal-to-child infection is associated with maternal factors of late testing, breastfeeding, substance abuse, and lower CD4 cell counts.[41] HIV-infected infants report serious lower respiratory tract illness.

In previous years, lymphoid interstitial pneumonitis/hyperplasia, reported in 25 percent of all children with acquired immunodeficiency syndrome, was associated with chronic cough, but this HIV-associated outcome rarely is reported with the advent of improved antiviral medications to suppress replication of HIV. Despite restoration of immunocompetence with HAART, lower respiratory tract infections (viral, bacterial, fungal) are still common occurrences in children infected with HIV.[18] An unexpected consequence of efficacious HIV-directed therapy in affected children may lead to increased risk for developing asthma through an immune reconstitution mechanism.[33] The diagnosis of HIV infection is established by viral diagnostic assays (polymerase chain reaction) for perinatally exposed infants younger than 18 months of age.[26] HIV antibody testing (enzyme-linked immunosorbent assay and confirmation assays [Western blot analysis, indirect fluorescent antibody assay]) can confirm infection in perinatally exposed infants 18 months or older. HIV serologic assays are not appropriate for HIV infection detection in children 18 months of age or younger because passively acquired maternal HIV antibodies may persist and confuse interpretation of a positive test in this age group.

Anatomic lesions that lead to pulmonary obstructive airway disease can simulate the complex of chronic bronchitis. An infant with chronic cough, poor feeding habits, and failure to thrive should undergo evaluation for gastroesophageal reflux and tracheoesophageal fistula, which are identified most easily by barium swallow, pH probe monitoring, and nuclear scan. Mediastinal tumors can produce extrinsic obstruction, leading to recurrent cough and wheezing. Congenital heart disease should be considered in this patient group and can be evaluated with chest radiography, electrocardiography, and echocardiography.

Respiratory tract irritants have been implicated as a cause of chronic cough, as documented in adult populations of industrial European nations.[40] An assessment of the public health impact of pollution in Austria, France, and Switzerland concluded that air pollution caused 6 percent of all mortality, or 40,000 attributable cases per year.[16] Nonindustrial, rural communities, such as the forest zone of Nigeria, report virtually no chronic bronchitis, whereas increased risk for development of respiratory disease (i.e., persistent cough, persistent phlegm, asthma) is noted in children residing in six cities in Northern China with the highest ambient air levels of particulate air pollution.[25] After exposure to urban air particulate matter, animal models with induced chronic bronchitis (exposure to 200 ppm of sulfur dioxide for 6 weeks) have shown pathologic changes consistent with exacerbation of chronic bronchitis—changes in ventilatory capacity and marked pulmonary inflammation.[4]

A correlation between tobacco smoking and reduced ventilatory capacity in adults has been reported by many investigators. Peat and associates[29] described teenagers in Sydney, Australia, with recurrent episodes of bronchitis with worsened lung function when coupled with tobacco smoking. A meta-analysis of 21 relevant publications on relationships between exposure to environmental tobacco smoke and lower respiratory tract infection in infancy and early childhood concluded that exposure to environmental smoke resulted in adverse childhood respiratory outcomes (hospitalizations).[17] In a study of approximately 65,000 nonsmoking Canadians 12 years or older, vehicular environmental tobacco smoke was associated with chronic bronchitis for children between 12 and 19 with odds ratios of 2.3 and 2.25 for children and older teens.[8] Tashkin and colleagues[38] further found in 300 individuals followed for 10 years that both tobacco and marijuana smoking appeared to be causally associated with the development of chronic bronchitis. These data suggest that it is not only imperative to prevent smoking in individual youth to prevent respiratory disease but also to gather a smoking history (tobacco and drugs) for household members and apprise them of the impact of their smoking on their children.

Other noxious agents associated with outdoor pollution have been associated with poor control of chronic cough complex diseases such as asthma. In Los Angeles, adults with asthma were more poorly controlled if they resided near areas of heavy traffic.[19] Similar findings of poorly controlled lung disease associated with traffic pollution have been documented in adult and pediatric patients in Lima, Peru.[3] Occupational exposures long have been cited for exacerbating pulmonary diseases and may be responsible for about 15 percent of chronic bronchitis and chronic obstructive pulmonary disease. Classic

examples of occupational exposures leading to increased risk for developing chronic cough are described in coal dust for miners in Great Britain and recently smoking and welding fumes in Northern European welders.[10,45]

EPIDEMIOLOGY AND ETIOLOGY

Differentiating the impact of clinical, social, and environmental factors on lower respiratory tract disease, including chronic bronchitis, has been problematic and has led to conflicting outcomes in epidemiologic assessments.[5,37] In addition, the lack of a standardized definition of chronic bronchitis in the pediatric literature leads to confusing interpretation of data when attempting to appreciate the prevalence or etiology of the disease complex. In Table 20-1, the data from Kubo and associates[15] separate acute recurrent bronchitis, asthmatic bronchitis, and chronic bronchitis, leading to a decrease in the prevalence from a proposed 46.4 percent (in the Arizona questionnaire) to 1.4 percent.

Considerable overlap also exists in evaluating etiologic agents for chronic bronchitis. The same viral agents proposed as the exacerbating factors of asthmatic bronchitis are implicated in exacerbations of chronic bronchitis,[11] including rhinoviruses, parainfluenza viruses, respiratory syncytial virus, influenza A and B viruses, adenoviruses, and enteroviruses. Persistent adenovirus infection has been implicated as a cause of childhood chronic bronchitis. In a study of 11 children with chronic bronchitis, transbronchial biopsy specimens revealed no evidence of persistent adenovirus infection (culture or polymerase chain reaction),[30] suggesting that viral infections may precipitate cough, but their roles in the pathologic findings associated with chronic bronchitis should be questioned.

Table 20-2 lists predominant bacterial pathogens isolated from sputum for a group of 40 pediatric patients with chronic bronchitis and exacerbations of cough and fever; these pathogens include *H. influenzae*, *S. pneumoniae*, and *Staphylococcus aureus*.[15] These bacteria also are implicated as etiologic agents in the triggering of asthmatic bronchitis. Neither *Mycoplasma* nor human metapneumovirus was included in this listing, but this simply may reflect the time frame (late 1970s) when the Kubo study was conducted.[27,42] Treatment of exacerbations of chronic bronchitis with antibiotic therapy usually is effective in reducing the volume of sputum and purulence during the acute infection but shows no parallel elimination of the cultured microorganisms.

TABLE 20-2 **Predominant Pathogens in Washed Sputum of Chronic Bronchitis (40 Cases)**

Pathogen	No. Cases
Haemophilus influenzae and *Streptococcus pneumoniae*	21 (52.5%)
H. influenzae	17 (42.5%)
Staphylococcus aureus	2 (5%)
Superinfection with gram-negative rods	
Pseudomonas aeruginosa	4
Klebsiella pneumoniae	2
Escherichia coli	1
Enterobacter cloacae	1

TREATMENT

When a specific diagnosis is found in association with chronic cough or wheezing, therapy is directed toward the primary disease entity and the clinical presentation of cough. Bronchodilators (β-adrenergic agents), anti-inflammatory agents (corticosteroids), and anticholinergic agents are used, when appropriate, for the treatment of chronic cough associated with asthma or acute exacerbations of chronic obstructive pulmonary disease.[36] Appropriate positioning techniques (prone 30 degrees), feeding schedules, and medications (e.g., gastrointestinal motility enhancers, proton pump inhibitors, or cholinergics) are indicated in the approach to infants with gastroesophageal reflux. Patients with hypogammaglobulinemia can be helped with supplemental intravenous immunoglobulin preparations currently available commercially (400 to 600 mg/kg per dose every 3 to 4 weeks) in an attempt to decrease the incidence of infections.

It is imperative that patients with chronic pulmonary diseases such as cystic fibrosis, asthma, or ciliary dyskinesias understand the pulmonary irritant effect of tobacco smoking, dust exposure, and air pollution. A change of occupation may be essential for their well-being. It also is imperative to stress the irritant effect of parental smoking on the already compromised pulmonary function of the child.

Management of chronic cough in children 14 years of age or younger is outlined in Figure 20-2. In the evidence-based guidelines for chronic cough, normal chest radiography and, as developmentally appropriate, normal spirometry suggest a "watch, wait, and review" approach to clinical management. Cough will spontaneously resolve for many children with normal chest radiographic examinations. The use of cough suppressants or over-the-counter cough medicine is discouraged, especially in very young infants who may experience significant drug-associated morbidity. Persistent cough should be reassessed clinically. For children with persistent dry cough, a trial of inhaled corticosteroids is recommended in this management algorithm and antibiotics for those with persistent wet cough.

When considered, antibiotic therapy for chronic bronchitis usually consists of amoxicillin 45 to 90 mg/kg every 24 hours, erythromycin 40 mg/kg every 24 hours, or, in adolescents and adults, tetracycline 25 to 50 mg/kg every 24 hours or quinolones for 5 to 10 days.[34] Methylxanthine therapy is used less frequently in chronic bronchitis care. When it is used, certain antibiotics, such as erythromycin, lead to elevated serum concentrations of theophylline, which renders toxicity more likely to occur.

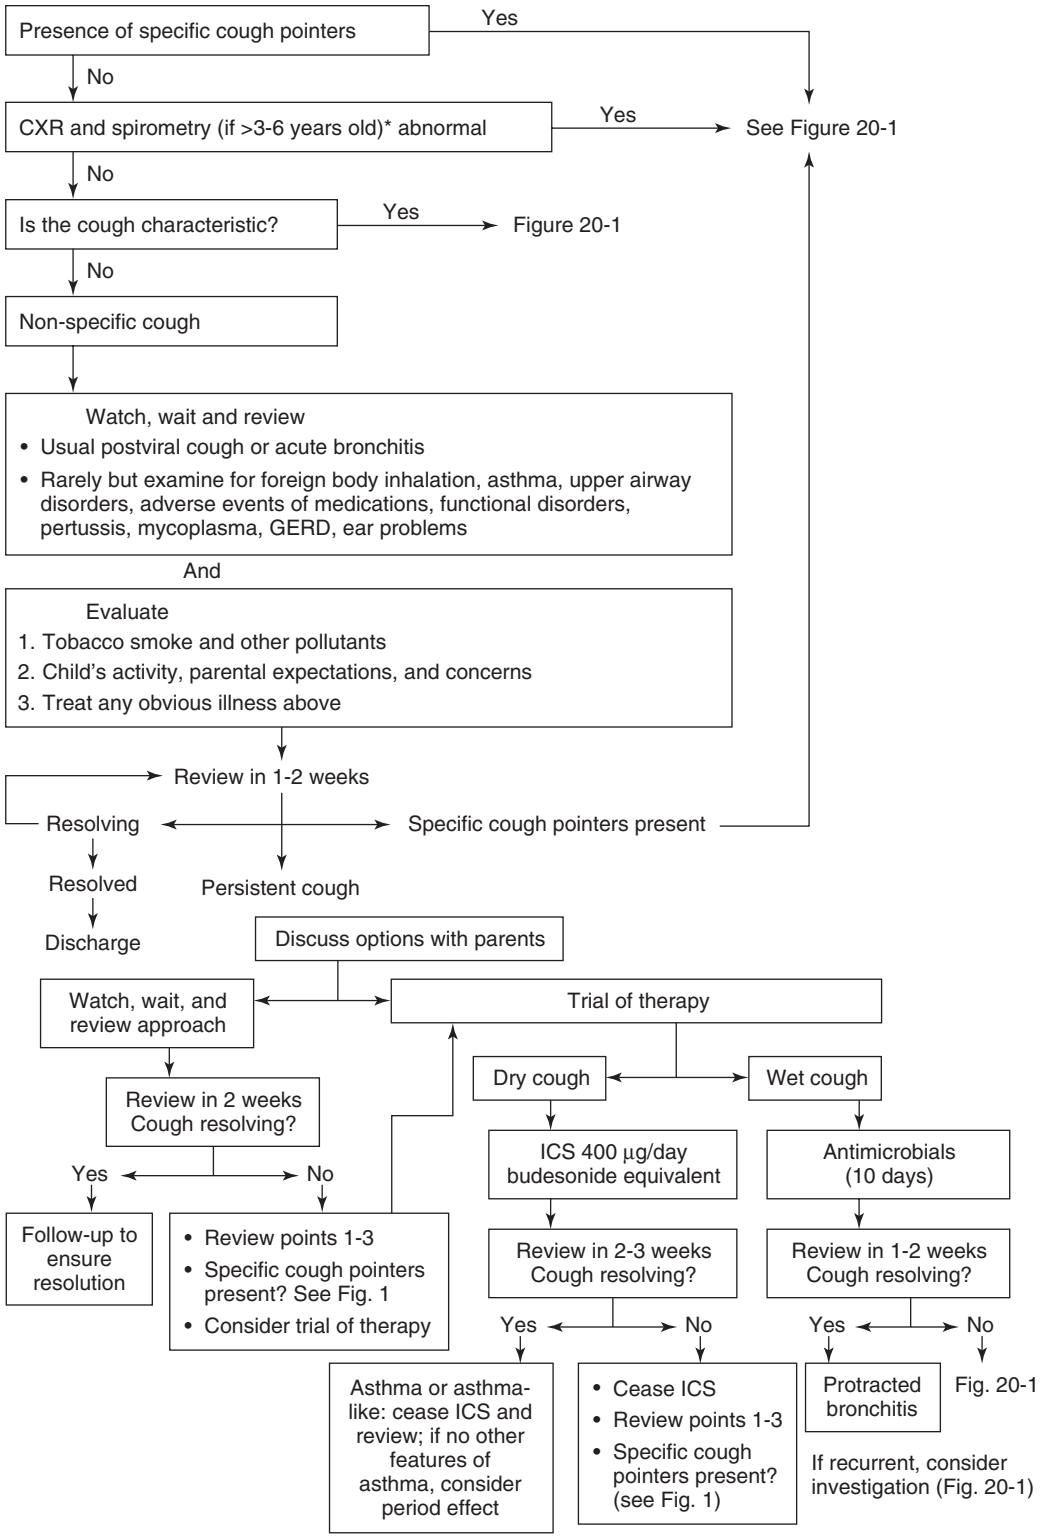

FIGURE 20-2 ■ Approach to a child younger than 15 years of age with chronic cough. *CXR,* Chest radiograph; GERD, gastroesophageal reflux disease; *ICS,* inhaled corticosteroids. (Modified from Irwin RS, Baumann MH, Blaser DC, et al. Diagnosis and management of cough executive summary: ACCP evidence-based clinical practice guidelines. *Chest* 2006;129:15–23S.)

Treatment with mucolytic agents in chronic pulmonary disease has not proved to have a significant impact except in adults with already advanced disease with multiple hospitalizations, and no evidence suggests that they are beneficial in children.[31]

As with patients with obstructive lung disease, attention must focus on careful and sequential monitoring of pulmonary function. The prognosis for chronic bronchitis varies and depends on the specific etiology of this syndrome.

HISTORY

Although all practicing pediatricians today are familiar with the term *bronchiolitis* and associate it with an acute clinical illness with the signs and symptoms of airway obstruction, it has been recognized in the medical literature for only a relatively brief period. In the early years of the 20th century, the term *capillary bronchitis* was used to describe an inflammatory illness of the smallest alveoli.[60] The condition could not be distinguished clinically from pneumonia, however, and whether the pathologic entity (i.e., bronchiolitis) ever occurred separately from pneumonia was doubted. In the 11th edition of *Holt's Diseases of Infancy and Childhood*,[77] published in 1940, capillary bronchitis is discussed only briefly and is considered under pneumococcal pneumonia. Acute bronchiolitis finally was listed as a heading in the sixth edition of the *Textbook of Pediatrics*,[131] published in 1954; even at that time, bronchiolitis was associated with interstitial pneumonitis.

In contrast to the delayed textbook recognition of bronchiolitis, good clinical descriptions were presented in journals. In 1941, Hubble and Osborn[79] published "Acute Bronchiolitis in Children," in which they described an epidemic of bronchiolitis involving 50 hospitalized children. Pratt,[146] in 1944, and Nelson and Smith,[132] in 1945, published excellent clinical articles. Studies in the late 1950s and early 1960s established the etiologic association of RSV and other viruses with acute bronchiolitis.[9,25,26,160]

ETIOLOGIC AGENTS

RSV is the major cause of bronchiolitis in infancy and virtually the only important etiologic consideration when major epidemics are occurring. Other agents cause smaller annual outbreaks. The frequency of infectious agents in the overall cause of bronchiolitis is shown in Table 21-1. These data were compiled from 12 reports in which respiratory illness in children was observed over an extended period, and in most instances numerous clinical illness categories were being studied. During major epidemics in the colder months in temperate climates, virologic and serologic studies indicate RSV as the cause in 80 percent or more of the cases, especially in the more severe ones. In nonepidemic situations, more than 50 percent of the isolates or instances of serologic evidence of infection are infectious agents other than RSV. Sporadic disease rarely is associated with more than a 50 percent association of infectious agent and illness, despite the fact that infections undoubtedly are the cause of sporadic and epidemic bronchiolitis.[120]

TABLE 21-1 **Infectious Agents Associated with Acute Bronchiolitis**

Infectious Agent	Relative Frequency (%)
Respiratory syncytial virus	50
Parainfluenza viruses	25
Type 1	8
Type 2	2
Type 3	15
Adenoviruses	5
Mycoplasma pneumoniae	5
Rhinoviruses	5-15
Influenza viruses	5
Type A	3
Type B	2
Metapneumovirus	5-10
Enteroviruses	2
Herpes simplex virus	2
Mumps virus	<1

Children surviving infantile bronchiolitis often have recurrent episodes of wheezing that, on clinical grounds, seem to be precipitated by upper respiratory tract infections. Studies designed to determine the infectious agents responsible for these repeated wheezing episodes have yielded variable results, presumably because they involve patients of different ages observed during different seasons of the year.[12,106,122-125] A comprehensive study based on more than a decade of observation of children from birth through 15 years of age[71] revealed that viruses and *Mycoplasma pneumoniae* are the most common etiologic agents (Table 21-2).[128] RSV is the most common cause of recurrent, wheezing-associated respiratory illness occurring in young children, including children who previously experienced bronchiolitis, which strongly suggests the identical nature of infection-related wheezing episodes occurring in children of different ages. With increasing patient age, rhinoviruses and *M. pneumoniae* account for most infection-induced wheezing episodes. Parainfluenza viruses and influenza viruses are important causes of such wheezing episodes throughout childhood, whereas coronaviruses and adenoviruses are less common causes in infancy. Human metapneumovirus and bocaviruses are more recently identified causes of bronchiolitis, and their relative importance as etiologic agents is being determined. RSV remains an important cause of wheezing in adolescents[71] and can cause airway obstruction in middle-aged and elderly individuals.[45]

The role of bacteria as primary agents, synergistically active participants, or secondary invaders in bronchiolitis has interested investigators for many years. No evidence has been found of a primary role for bacteria in bronchiolitis of infants.[9,105] The data on synergistic viral-bacterial infections also are unconvincing. Wood and colleagues[205] in 1954 and Sell[165] in 1960 reported results of studies in which bacteriologic and serologic evidence tended to associate *Haemophilus influenzae* infections with bronchiolitis. Some of the children from these studies later were shown serologically to have had RSV infection.[28] Later studies showed evidence of mixed viral-bacterial infections in bronchiolitis[108,134] and other lower respiratory tract illnesses.[134]

These serologically defined mixed infections were found no more commonly among patients with bronchiolitis than among patients with mild upper respiratory tract disease, whereas RSV was recovered 10 times as often from patients with lower respiratory tract disease as from patients with upper respiratory tract disease alone.[108] Although debate continues about whether the

TABLE 21-2 **Principal Agents Recovered from Children of Different Ages with Wheezing Precipitated by Infection**

isolation of *H. influenzae* from the airway of infants with bronchiolitis represents secondary infection, most data indicate that a significant role for mixed viral-bacterial infection in bronchiolitis of infancy is unlikely to exist. Bacterial superinfection is an uncommon occurrence in bronchiolitis (at least in developed countries) and is discussed later in the section on complications and prognosis.

The association of asthma and infectious illnesses was appreciated throughout the 20th century. Initial reports tended to relate bacterial agents to wheezing; in 1909, Carmalt-Jones[21] reported improvement of patients with asthma in association with injections of a bacterial vaccine. Throughout the first half of the 20th century, "bacterial allergy" was the main consideration in infection-related wheezing, and controversy raged about the therapeutic merits of bacterial vaccines. Despite widespread use of bacterial vaccines in the treatment of infectious asthma, no evidence exists that bacterial organisms of the normal flora precipitate asthmatic attacks.[68,78,127] More recent, large retrospective reviews have shown the rarity with which bacterial infection complicates bronchiolitis, even in severe cases.[148,151] Generally, after a diagnosis of RSV, metapneumovirus, rhinovirus, or parainfluenza virus infection has been established, antibiotic courses started empirically can be safely stopped.

EPIDEMIOLOGY

Bronchiolitis predominantly is a disease of infancy, although an identical disease occurring in older children arbitrarily may be referred to as another diagnostic entity. In a study involving 1148 children, the peak age of incidence was 2 to 6 months, with more than 80 percent of the cases occurring during the first year of life.[141] In a study of families in or near Houston, Texas, rates of RSV infection were 68.8 per 100 children in the first year of life and 82.6 per 100 children in the second year, including many reinfections. Lower respiratory tract illness was caused by RSV in 22.4 of 100 children in the first year of life. Of all RSV infections occurring in children younger than 12 months of age, one third were accompanied by lower respiratory tract illness. Although the attack rate of RSV decreased with age, the frequency with which lower respiratory tract disease occurred among individuals infected remained constant (Table 21-3), at least until they reached 4 years of age.[56,57] In Tucson, Arizona, a study of 1179 children enrolled in a health maintenance organization found that the rate of lower respiratory tract illness in the first year of life was 32.9 episodes per 100 children; 60 percent of these episodes were diagnosed as bronchiolitis.[208]

TABLE 21-3 **Attack Rates of Respiratory Syncytial Virus**

Age in Months [per Welliver] (n)	Infections per 100 Child-Years	LRTI per 100 Child-Years	LRTI per 100 Infections
0-12 (125)	68.8	22.4	32.6
13-24 (92)	82.6	13	15.8
25-36 (65)	46.2	10.8	23.3
37-48 (39)	33.3	7.7	23.1

LRTI, lower respiratory tract infection.
Data from reference 57.

Studies in the Washington, D.C., area[92] and in North Carolina[71] estimated the risk for hospitalization for bronchiolitis among infants up to 1 year old to be 10 per 1000. A combined study involving 10 centers in Great Britain[154] concluded that the frequency of hospitalization for lower respiratory tract disease (predominantly wheezing) caused by RSV was 1 per 114 infants younger than 1 year of age and 1 per 476 children younger than 5 years of age. Peak rates of hospitalization were observed for children 1 to 3 months old (1 in 56).

More recent studies suggest that the rate of hospitalization for bronchiolitis may be higher currently than in the just-mentioned older studies. A study of the Tennessee Medicaid population found that the frequency of

hospitalization for bronchiolitis was 4.4 and 1.5 per 100 child-years of observation for infants infected in the first and second 6 months of life, respectively.[15] Approximately 123,000 infants younger than 1 year of age are hospitalized annually with bronchiolitis, with RSV infection accounting for 51,000 to 82,000 of these hospitalizations. Including cases diagnosed as pneumonia, RSV infection results in 70,000 to 120,000 hospitalizations.[167]

Between 1979 and 1997, an average of 95 bronchiolitis-associated deaths occurred annually, with 77 percent occurring during the RSV epidemic season. Including fatal cases of bronchiolitis or pneumonia, RSV infection might have resulted in 171 to 510 deaths annually.[168] The yearly incidence of hospitalization for bronchiolitis increased from 12.9 per 1000 infants in 1980 to 31.2 per 1000 in 1996, suggesting an increased severity of illness developing during this interval.[167] More frequent hospitalization may also be a result of an increased use of pulse oximetry to determine the need for hospitalization.[111] In concert with this, a subsequent study showed that the rate of RSV hospitalizations was stable from 1997-2006, at a rate of 132,000 to 172,000 hospitalizations annually in children younger than 5 years old in the United States.[178]

Epidemic bronchiolitis caused by RSV is markedly seasonal in temperate climates, with peak activity occurring from January to April annually and with virtually no activity seen from August to October.[92] Sporadic bronchiolitis cases caused by other agents are seen throughout the year. In their study of 1179 cases, Kim and associates[92] found that 77 percent of the cases of RSV infection occurred between December and June. The lowest incidence occurred in August (2%). Regional differences can be striking. In Miami, RSV activity occurs year round, with the most cases in September and October. Epidemics usually begin in October in other southern states, although still earlier than in the Northeast. Further north (Winnipeg, Canada, and Alaska), the duration of the RSV season again becomes longer and cases occur essentially year round. Near the equator, temperature and humidity are positively associated with the number of bronchiolitis cases. In contrast, further from the equator (in either direction), temperature and humidity are inversely associated with bronchiolitis cases. Ultraviolet radiation is negatively associated with bronchiolitis in several regions.[210] In contrast to yearly epidemics of RSV infection in the United States and United Kingdom, with identical peak months of occurrence each year, RSV occurs in biennial epidemic cycles in Croatia,[126] Switzerland,[39] Sweden,[155] Finland,[194] and Germany,[184] with peaks alternating between December and January in 1 year and March and April in alternate years. No explanation has been established for the biennial occurrence of these epidemics.

Bronchiolitis occurs more frequently in boys; the male-to-female ratio is approximately 1.5 : 1.[49] In older children, wheezing attributable to viral and mycoplasmal infections also occurs more frequently in boys (male-to-female ratio 1.35 : 1) until they reach 9 years of age, when the incidence becomes equal for the sexes.[71] Crowding may be a major determinant of hospitalization rates for lower respiratory tract illness caused by RSV, with the incidence of hospitalization for infants 1 to 3 months old residing in rural, urban, and heavily industrialized areas of Great Britain being 1 in 80, 1 in 60, and 1 in 40, respectively. The figures for all children younger than 5 years of age were 1 in 714, 1 in 588, and 1 in 227, respectively.[154] Studies from Tucson, Arizona, indicate that many socioeconomic factors, including absence of breast-feeding, low level of maternal education, and exposure to cigarette smoke, are associated with an increased risk for developing lower respiratory tract infection at the time of infection with RSV. The greatest risk was conferred by sharing sleeping quarters with two or more individuals.[208]

CLINICAL PRESENTATION

Acute bronchiolitis occurs most commonly in infants 1 to 12 months of age. In most instances, the patient's history reveals exposure to an adult or older child with a common cold or other trivial respiratory tract infection. Occasionally, as in the daycare setting, the child is exposed to other children with more marked respiratory illness. After exposure, the incubation period is 5 to 7 days. The initial signs include copious nasal discharge (often serous in the early stage), cough, irritability, poor feeding, and vomiting in some cases. Slightly more than 50 percent of infants have fever, with rectal temperatures ranging from normal to 40.6° C (105.4° F) (mean, 39° C [102° F]).[153] Nasal congestion with tenacious secretions and progressive cough and dyspnea dominate the clinical picture.

Symptoms of upper respiratory tract infection persist for a few days, and the onset of lower respiratory tract infection usually is precipitous, with the time of the onset of wheezing often being recognizable from the caretaker's description of the illness. The maximum severity of illness generally is attained within 24 to 36 hours of the first signs of lower respiratory tract illness.[16] Apnea may occur and may be sufficiently severe to require mechanical ventilation.[17]

At the time of hospital admission, all patients have cough and evidence of respiratory distress. The pulse is rapid, and the respiratory rate usually is 40 to 80 breaths per minute. The breathing is labored, with flaring of the alae nasae; grunting; abdominal breathing; and supraclavicular, subcostal, and intercostal retractions. The degree of retraction of the lower chest wall may be an accurate indicator of the severity of the illness. Wheezing is best heard by auscultation over the upper anterior chest but often is audible without the use of a stethoscope, and the chest is full. Hyperresonance may be detected on percussion, and auscultation generally reveals harsh rhonchi, high-pitched or low-pitched expiratory wheezes, or fine inspiratory rales. Occasionally, wheezing is not audible despite other evidence of airway obstruction. A prolonged expiratory phase of breathing may occur, suggesting the presence of a more severe degree of illness. Cyanosis also occurs in severe cases.

Other findings include a mild conjunctivitis in one third of cases, pharyngitis of varied severity in approximately half of affected infants, and otitis media in 5 to 15 percent of cases. The abdomen frequently appears distended, and the liver and spleen usually are palpable; the organs are not enlarged but are pushed down because of hyperexpansion of the lung.[1]

The duration of the hospital course of bronchiolitis varies. Significant improvement occurred in half of the cases within 2 days in one large study.[139] In the same study, approximately one third of the cases had a gradual course without evidence of clear-cut improvement at any one time; 71 percent of the patients were afebrile by the third hospital day. In another study done more than 25 years later,[58] the average duration of hospitalization was 3.4 days. Longer stays were required for infants with initial oxygen saturations of less than 90 percent and infants younger than 6 weeks at the onset of illness. Reasonable criteria for admission in otherwise healthy infants seem to include hypoxia (i.e., oxygen saturation of <90% to 92%), age younger than 6 weeks, and a degree of respiratory distress sufficient to reduce fluid intake to inadequate levels. Other criteria include apnea, immunodeficiency, premature birth, and the presence of significant underlying heart or lung disease. Most patients can be discharged from the hospital within 2 to 3 days after admission, although mild wheezing still may be present for several days or even weeks thereafter.[13]

In 121 hospitalized patients, the total white blood cell count was less than 12,500/mm^3 in 74 percent and in 15 determinations had more than 60 percent neutrophils.[2] In another study, a mean leukocyte count of 16,000/mm^3 was determined for children with lower respiratory tract disease, including bronchiolitis, as was an increased percentage of band form neutrophils compared with that of a control group.[153] As in most infections, eosinophil counts in peripheral blood are reduced at the time of acute RSV infection.[52] Nonetheless, some patients maintain detectable eosinophilia in peripheral blood; these infants may be more likely to develop childhood asthma.[40]

Although impaired oxygenation is usually present in infants with respiratory distress, cyanosis may not be evident, even in the presence of markedly reduced oxygenation.[31,169] The respiratory rate is related inversely to the degree of oxygenation except when respiratory failure is imminent. In mild to moderate cases, carbon dioxide retention does not occur because the alveoli that are functioning can compensate for alveoli that are not ventilated. In severe disease, the blood pH is low and the $Paco_2$ is elevated.[31,169] The technique of pulse oximetry has obviated the need for arterial blood gas sampling except perhaps in severe cases in which hypercarbia is a concern.

In certain patients, clinical findings (e.g., degree of chest wall retractions, wheezing) often are out of proportion to the degree of hypoxia as measured by pulse oximetry.[129,193] Infants with marked dyspnea must be evaluated carefully because respiratory failure may occur precipitously, despite their reassuring oximetry readings. Once infants are hospitalized and stabilized, subsequent deterioration to the point of requiring intensive care is unusual, occurring in less than 2 percent of cases. Respiratory rates of 63 breaths per minute and oxygen saturations less than or equal to 88 percent on admission were weakly associated with such eventual deterioration in one study.[16]

The radiographic appearance of the chest in bronchiolitis varies considerably.[96] Anteroposterior radiographs may be normal in mild cases or may reveal hyperinflation in the absence of hypoxia. In moderate to severe illness, radiographs often appear exceptionally clear because of hyperinflation. The diaphragms often are flattened or depressed. The costophrenic angle is less acute, and the hilar vascular shadows are stretched. Frequently, areas of atelectasis may give the appearance of pneumonitis, although true consolidation is a rare occurrence. The heart usually appears small. On the lateral radiograph, the diaphragm is depressed markedly and reversal of the normal convexity frequently may be seen. The anteroposterior diameter of the chest is increased.

With recurrent wheezing episodes, the prodrome may be considerably shorter in duration with little or no fever and minimal coryza. In these children, differentiation of infection-induced wheezing from more conventional asthma becomes essentially impossible clinically.[202]

PATHOPHYSIOLOGY

The pathophysiology of bronchiolitis deservedly has been the focus of numerous investigations. Several original theories can be discounted reliably, whereas others warrant further study. Pathologic examinations of the lung in bronchiolitis or human airways in organ culture[72] reveal necrosis of the respiratory epithelium with destruction of the ciliated layer; mononuclear cell invasion of the peribronchial tissues and alveolar interstitium; edema of the submucosa and adventitia; and obstruction of small airways with dense plugs consisting of dying epithelial cells, fibrin, and inflammatory cells. In contrast to asthma, mucin (periodic acid–Schiff positive material) usually is absent in fatal bronchiolitis.[200] An associated interstitial pneumonitis often is present, and patchy areas of atelectasis frequently are noted.[203]

The predominant cell types present in the lung of fatal cases are macrophages and neutrophils. Lymphocytes bearing CD4 (helper cells), CD8 (cytotoxic cells), and CD56 (natural killer cells) antigens are almost absent in fatal bronchiolitis cases.[200] In contrast to the findings in fatal cases, CD8 lymphocytes were present in the lung tissue obtained from a nonhospitalized child with a mild lower respiratory tract infection caused by RSV who died in an automobile accident.[84] Even in surviving infants, CD8 lymphocyte counts are less than 1 percent of the total cells in bronchoalveolar lavage fluids[44] and only appear in respiratory tract secretions of subjects with severe forms of disease after illness has largely resolved.[69,107] These findings suggest that CD8 lymphocyte responses are necessary for early control of RSV infection and that severe disease is perhaps related to an absence of CD8 responses. Cytokines characteristically released by CD4 and CD8 cells (interleukin [IL]-2, IL-4, IL-5, IL-13, and

interferon-γ) are present only in low concentrations in nasopharyngeal and tracheal secretions of infants with severe lower respiratory tract infections caused by RSV.[14,54,200] Staining for markers of apoptosis (caspase 3 and Fas) is positive in infected epithelial cells,[200] suggesting that recovery from primary infection depends on the antiviral activity of phagocytic cells, induction of apoptosis, and perhaps the activity of other innate immune mechanisms. Strong innate immune responses occurring early in the course of infection may limit the eventual degree of illness.[11] Rhinovirus bronchiolitis appears to occur more frequently in subjects with preexisting atopic dermatitis and eosinophilia, suggesting that allergic pathways may contribute to bronchiolitis caused by this virus.[98,150]

Recovery from bronchiolitis apparently is complete histologically,[130,203] although plugging of the airway still was prominent in an infant 5 weeks after having an acute episode of bronchiolitis. This infant had experienced an apparent full clinical recovery before eventually dying of acute pneumococcal pneumonia.[130]

Infants may be particularly prone to the development of severe illness as a result of infection of the small airways for many reasons, including the small diameters of their airways. The infant lung is deficient in collateral alveolar ventilation through the pores of Kohn, which develop only in later life.[109] Atelectatic areas therefore cannot be re-expanded readily. Other studies have shown that the small airways in children younger than age 5 years contribute fivefold to sevenfold more to total airway resistance than do small airways of adults.[76] Viral infections involving small airways in young children are more likely to present as more serious clinical manifestations than similar infections in adults. Nonetheless, these abnormalities exist in all infants, whereas most infants infected with RSV do not develop lower respiratory tract illness. This suggests that host or environmental factors may be involved in determining the pathogenesis of RSV infection. Environmental factors are listed in Table 21-4, and potentially important host factors are described later.

One factor that may predispose to the development of lower respiratory tract illness after RSV infection is the infecting dose of virus. Infants with greater quantities of RSV in their nasopharyngeal secretions are more likely to exhibit severe illness.[18] In fatal cases, abundant virus is evident in epithelial cells plugging the airway lumen by immunohistochemical staining.[200] The fact that crowding is associated with greater risk for developing lower respiratory tract infection also suggests the importance of the initial inoculum in causing disease.[207,208]

Another risk factor for the development of lower respiratory tract infection may be the relative diameter (or degree of intrinsic constriction) of the airway. When pulmonary function testing is completed on healthy infants before lower respiratory tract infection occurs, certain infants have lower air flows in smaller airways (and presumably more narrow airways) than do other infants. When observed prospectively, these infants are more likely to develop wheezing early in life than are infants with better airflow.[113,115] These abnormalities of lung function no longer are associated with an increased risk for wheezing after the child reaches 3 years of age. Instead, evidence of atopy becomes the principal risk factor for recurrent wheezing.[115]

Long-term follow-up studies of infants who had bronchiolitis reveals reduced airflow in small airways in later childhood. Studies of adolescents reveal reversibility of this restriction of airflow after receiving bronchodilator treatment, indicating the airways were constricted, but not stenotic, in early life.[176] Several studies have shown that the airways of infants are intrinsically more reactive to bronchospastic stimuli than are airways of older children,[104,183] particularly children from families with asthma.[209] How long this increased reactivity persists is unknown, and no study has shown that infants with greater degrees of hereditary airway hyperreactivity are more likely to develop bronchiolitis or recurrent virus-induced wheezing. In later childhood, repeated occurrences of viral infections are necessary to sustain this increased reactivity.[191]

In addition to the hereditary airway hyperreactivity, viruses themselves may induce increases in reactivity. Viral infections that clinically appear to be restricted to the upper respiratory tract in adults and children

TABLE 21-4 **Factors Associated with an Increased Risk and Severity of Bronchiolitis and of Postbronchiolitic Morbidity**

Factor	Increase in Frequency	Increase in Severity	Increase in Later Morbidity
Crowding	+++	+++	?
Passive smoking	+++	+++	++
Male gender	+	++	++
Absence of breast-feeding	+	+	?
Family history of asthma	±	±	±
Personal atopy	–	–	+++

Airway hyperreactivity	–	+	++
RSV-specific IgE responses	++	++	++

+++, implies strong relationship; ++, implies moderate relationship; +, implies weak relationship; ±, implies controversial relationship; –, implies no relationship; *?*, implies unknown relationship.
RSV, respiratory syncytial virus.
Data from references 19, 56, 64, 71, 101, 113-115, 117, 154, 170, 180, 195, 196, 199, 201, 207-209, and 211.

nonetheless result in transient, increased constrictive responses of the airway to a variety of stimuli, including histamine, irritants, and other agents, and small airway dysfunction.[2,4,30,42] Whether these minor changes contribute to the airway obstruction observed in bronchiolitis is doubtful, in that they are of much lesser magnitude than is the markedly increased reactivity that is observed in asthmatic individuals after exposure to allergens. These virus-induced changes were observed in all infected individuals, including subjects who did not experience wheezing at the time of the virus infection. If airways already are hyperreactive in infants, on a hereditary basis or as a result of a preceding viral infection, the subsequent stimulus of RSV infection may be sufficient to cause airway obstruction.

Immunologic deficits may be expected to lead to more severe forms of virus-induced respiratory illness. Studies of the antibody response to RSV infection in serum and in respiratory secretions show, however, that the nature of responses generally is similar among patients with bronchiolitis or simple upper respiratory tract illness alone caused by this agent.[89,197] Antibody-directed cellular cytotoxicity expressed against tissue culture cells infected with RSV also is similar in patients with all forms of illness caused by RSV.[88,163] Although investigators have shown that cells infected with RSV can activate complement through classic and alternative pathways,[175] studies suggest that in vivo activation of the complement cascade occurs with equal frequency among patients with all forms of illness caused by the virus.[88] Repeated RSV infections in early life may occur because antibody formed after primary RSV exposure has a low ability to bind to neutralizing epitopes on the virus.[34,50]

The concept that serum IgG antibody to RSV, acquired by vaccination or transplacentally, might sensitize the host has been dispelled by results of studies showing that severe bronchiolitis may occur in the absence of circulating antibody[141] and that titers of maternal antibody correlate with protection against infection caused by the virus.[56,135]

Lymphocyte hypersensitivity has been suggested to play a role in the development of severe bronchiolitis. Original field trials showed that a formalin-inactivated RSV (FI-RSV) vaccine induced humoral and cell-mediated immune responses to the virus. Nonetheless, vaccinated subjects manifested more severe forms of illness than did unvaccinated controls when subjects in each group subsequently were infected naturally.[93] Cell-mediated immune responses to viral antigen were greater among recipients of this FI-RSV vaccine compared with control subjects who previously had experienced natural infection.[94] The resulting disease in vaccine recipients was similar in form to bronchiolitis, and the idea that natural RSV bronchiolitis is a consequence of lymphocyte hypersensitivity to the virus has persisted.

Nonetheless, it seems unlikely that the illness that followed FI-RSV vaccination is mediated in the same way as that following natural bronchiolitis. The two FI-RSV vaccine recipients who died after having subsequent natural infection had numerous lymphocytes and eosinophils present in the lung, which is not the case after natural RSV infection.[84,93,130,200] Infants surviving RSV infection after receiving the FI-RSV vaccine had high eosinophil counts in peripheral blood, which also is unusual in natural RSV infection.[52] In addition, cytotoxic T-lymphocyte activity is not detected easily in infants after bronchiolitis,[6] and more recent autopsy studies have shown the virtual absence of CD4 and CD8 antigen-positive cells in the lung.[200] Although the development of cell-mediated cytotoxic antiviral responses may be protecting individuals with milder disease, little reason exists to contend that lymphocyte hyperresponsiveness contributes to severe bronchiolitis.

Immediate hypersensitivity to viral antigens has received much consideration as a potential contributing factor in bronchiolitis. The association of a family history of asthma with the development of bronchiolitis in infancy remains controversial.[101,171] Production of virus-specific IgE and subsequent release of mediators of bronchoconstriction have been documented, however, in infants hospitalized with bronchiolitis caused by RSV and the parainfluenza viruses.[19,196,198,199] In bronchiolitis caused by RSV, the quantities of virus-specific IgE produced and histamine present in respiratory secretions correlate with the severity of illness, as measured by degree of Pao_2.[199] Leukotriene C_4 is a product of mast cells and eosinophils primarily, although also epithelial cells and macrophages, and is a potent stimulant of airway smooth muscle constriction and mucus secretion. This mediator is released into the airway in acute bronchiolitis,[189] as is the bronchoconstrictive agent histamine.[172,199] In addition, prostaglandins and metabolites can be detected in secretions and blood after bronchiolitis.[153] Thus, several mediators of airway obstruction that are released in response to the interaction of IgE with antigens are released in subjects with bronchiolitis.

A possible role for eosinophils in the pathogenesis of bronchiolitis is supported by the finding of increased concentrations of eosinophil cationic protein in secretions of infants with bronchiolitis and (among high responders) an overall correlation of concentrations of this protein with the degree of hypoxia.[52,53] Peripheral blood eosinophil counts are depressed during the acute phase of most infectious diseases, including RSV infection. Nonetheless, eosinophil counts in peripheral blood are higher in infants with bronchiolitis than in infants with upper respiratory tract illness only, particularly in boys.[52] This finding is notable because boys generally have more severe forms of bronchiolitis. A contrasting viewpoint is that eosinophils contribute to the clearance of viruses after infection. This view is supported by the fact that eosinophils contain enzymes with ribonuclease activity, which inactivates RSV.[36,37] IgE-dependent and eosinophil-dependent mechanisms may be important in recovery from viral infections, much as they are in recovery from parasitic infections.

The airways of asthmatic individuals are infiltrated by T lymphocytes (predominantly T-helper lymphocytes) and eosinophils. T-helper cells can be classified as type 1 (Th1), which produce primarily interferon-γ and IL-2, or type 2 (Th2), which produce IL-4, IL-5, IL-13, and others. This finding is important because IL-4, IL-5, and IL-13 are important factors in promoting IgE synthesis and eosinophil migration. Asthma is thought to be

induced by a Th2 bias in the airway. An attractive hypothesis is that RSV infection induces airway obstruction and wheezing by inciting the same type of Th2 responses as observed in asthma. However, although interferon-γ and IL-4 are found in respiratory secretions of infants with RSV bronchiolitis, IL-5 and IL-13 rarely are detectable in serum or secretions,[54,189] suggesting that bronchiolitis is not characterized by a Th2 lymphocyte bias. RSV infection in infancy does not induce a long-term Th2 lymphocyte cytokine bias lasting into later life.[23]

Chemokines are proteins released by airway epithelial cells, inflammatory cells, fibroblasts, and other cell types that are chemotactic for leukocytes. A failure to initiate strong chemokine responses at the onset of RSV infection has been linked to more severe disease outcomes, possibly because innate immune mechanisms are not activated in a timely fashion.[11] In contrast, excessive production of the chemokine MIP-1α has been linked to the development of greater degrees of hypoxia during RSV infection.[11,54] Abnormal chemokine responses, rather than Th2 cytokine responses, may underlie the pathogenesis of bronchiolitis and thus may represent therapeutic targets.

DIFFERENTIAL DIAGNOSIS

A tendency exists to attribute all infantile respiratory distress occurring after the immediate neonatal period to bronchiolitis. The list of causes of infantile dyspnea consists of conditions that are associated with upper and lower airway obstruction, however. Recognition of upper airway obstructive disease should cause little difficulty because the problem is one of distress with inspiration rather than air trapping. Illnesses that cause lower airway obstructive disease and diseases that suggest this problem are listed in Table 21-5.

The differential diagnosis of allergic disease causes the most difficulty. Generally, the first episode of allergic respiratory disease, when associated with infection, cannot be separated from bronchiolitis by any objective measures. Anatomic defects such as vascular rings can cause obstruction of the airway at many locations; inspiratory or expiratory distress, or a combination, can occur. Frequently, a child with an anatomic defect does not have any detectable difficulty until a trivial respiratory tract infection occurs, which complicates the diagnostic picture.

Foreign bodies should be considered even in very young infants. Gastroesophageal reflux disease has become recognized as a frequent cause of wheezing in young infants. Because of its obvious therapeutic implications, bacterial pneumonia is the most important differential consideration, although wheezing occurs rarely in association with bacterial pneumonia.[108,118]

TABLE 21-5 **Differential Diagnostic Considerations in Acute Bronchiolitis and Infectious Asthma**

Allergy
Asthma
Allergic pneumonias (e.g., allergic aspergillosis)
Anatomic cause
Vascular ring, lung cysts, lobar emphysema
Pneumothorax, hydrothorax, chylothorax
Foreign body
Circulatory failure
Congenital and acquired heart disease
Anemia
Nephritis
Infections
Viral, chlamydial, rickettsial, mycoplasmal, bacterial, and fungal pneumonias
Migrating parasites
Irritants
Inhalation of toxic substances (e.g., chlorine gas)
Aspiration pneumonia
Gastroesophageal reflux
Metabolic cause
Poisons (e.g., salicylate)
Acidosis

DIAGNOSIS

Because bronchiolitis and infectious asthma are clinical diseases with arbitrary boundaries and multiple etiologic agents, outlining a method for establishing specific diagnosis is difficult. When illness is epidemic, RSV usually is the cause. In nonepidemic situations, a careful history and appropriate laboratory studies and radiographs should be considered to exclude the other differential diagnostic possibilities that are listed in Table 21-5.

A specific etiologic diagnosis can be made by the isolation of virus from the nasopharynx. The diagnostic virologic facilities of many medical centers enable the isolation in tissue culture of RSV, parainfluenza viruses, influenza viruses, adenoviruses, rhinoviruses, enteroviruses, and herpesviruses. The use of the shell vial technique has been applied to RSV infection with success.[174] Until recently, rapid detection of viral antigen of RSV directly in nasopharyngeal secretions by commercially available (e.g., enzyme-linked immunosorbent assay) or fluorescent antibody techniques has been the method of choice in most laboratories.[185] The accuracy of these techniques often is superior to that of standard cell culture (at least in infants) because antigens remain stable under transport conditions that inactivate live virus. Gradually, the technique of amplifying small quantities of RNA of respiratory viruses simultaneously from clinical specimens is replacing earlier methods. Currently, polymerase chain reaction techniques can test for as many as 15 respiratory viruses simultaneously in respiratory secretions.[136]

TREATMENT

The cornerstone of therapy for bronchiolitis is the administration of oxygen and correction of fluid deficits.

Most patients hospitalized for bronchiolitis can be managed successfully and discharged within 48 to 72 hours when given no further therapy than supplemental oxygen and careful fluid rehydration.[35,142,192] Oxygen saturation values obtained at the time of hospitalization have been used to predict the duration of hospitalization[166,192] and eventual deterioration and need for care in a pediatric intensive care unit after hospitalization.[16] Oxygen saturation is usually maintained at 92 percent or higher, although it has been suggested that an overreliance on oxygen saturation values as evidence for the need for hospitalization may lead to unnecessary admissions or needlessly prolonged stays.[161] Blood gas determinations should be obtained when indicated by clinical findings (e.g., cyanosis, agitation), because pulse oximetry is less sensitive for detecting hypoxia than is arterial blood gas sampling. Oximetry cannot detect increases in Pco_2 that may indicate impending respiratory failure.

A common practice has been to place children with bronchiolitis in tents and administer mist vigorously. Although oxygen should be humidified, the use of mists and aerosols except to deliver specific antiviral therapy is discouraged; mist can act as an irritant, causing reflex bronchoconstriction, and the water usually does not reach the lower airways.[7] Although dehydration is a potential problem in children with bronchiolitis because of reduced oral intake and vomiting, care must be taken not to overhydrate such patients. Edema is an important part of the pathology of bronchiolitis, so administration of excessive amounts of intravenous fluids may contribute to obstruction of the airway.

β-Adrenergic bronchodilators have been used frequently in bronchiolitis. Slight improvements in airflow, in oxygenation, and in clinical illness scores have been reported,[67,95,103,159] but these effects are not meaningful clinically; hospitalization is not prevented, and hospital stays are not shortened.[35,47] Improvements observed after the administration of the first dose of these compounds usually are not sustained after administration of subsequent doses. In one study, oral and aerosolized β-adrenergic agents were compared with inactive substances given by the corresponding route. The degree of improvement was the same in all four groups, arguing against a benefit of β-adrenergic agents in bronchiolitis.[51] This is not surprising, given the absence of evidence that bronchoconstriction occurs in bronchiolitis. Older individuals with infectious asthma may be more likely to respond to these agents, but viral infections remain the most common precipitant of childhood wheezing either managed on an outpatient basis or requiring hospitalization.[83,85] This suggests that children of any age with virus-induced wheezing do not respond dramatically to medications commonly used to treat asthma.

In the past, epinephrine often was administered subcutaneously to older infants in an attempt to differentiate allergic disease from true bronchiolitis. This approach rarely was successful in differentiating one illness from the other or in improving the condition of the patient. Some studies have suggested, however, that use of aerosolized, racemic epinephrine produces greater improvement than the use of β-adrenergic aerosols alone.[159] Compounds containing epinephrine could be more effective in reversing airway edema than are β-adrenergic agents. Generally, however, the minor improvements in pulmonary function are not meaningful clinically, because the length of stay in the intensive care unit or in the hospital is not reduced by the use of epinephrine.

Aerosols of ipratropium also have been administered in bronchiolitis without observable benefit.[164] Possible explanations for poor responses to bronchodilators include a paucity of β-adrenergic receptors in infancy[157]; decreased amounts of smooth muscle capable of responding to bronchodilators surrounding the terminal airways[152]; the nature of the airway obstruction itself (intense plugging with cellular debris)[200,204]; and, presumably, persistence of virus in the airway, stimulating continued inflammation or release of bronchoconstrictive mediators or both.

Trials of α- or β-adrenergic aerosols may be attempted in seriously ill patients, although persistence with these approaches in the absence of an initial response may prove harmful.[80,138] A child treated for croup with multiple doses of racemic epinephrine developed ventricular tachycardia and a small myocardial infarction,[20] emphasizing the need to avoid the careless use of these compounds in viral respiratory tract infections.

Corticosteroids have been employed repeatedly in treating bronchiolitis. Controlled studies have failed to reveal any benefit in terms of prevention of hospitalization, reduced duration of hospitalization, reduced need for intubation, or reduced frequency of recurrent wheezing episodes after bronchiolitis.* In a child with nonrespiratory indications for the administration of corticosteroids, these drugs need not be withheld because of fear of complications, although the duration of viral shedding may be extended in individuals treated with corticosteroids. Combinations of salbutamol and dexamethasone also have been evaluated but usually show minimal benefit.[182] One study suggested some benefit for this combination, but differences observed were short of statistical significance.[144]

Corticosteroids have also been used to prevent recurrent wheezing in preschool-aged children. They have been more effective in those children with atopic eczema and who were known to be sensitive to aeroallergens.[5,62] Corticosteroids have been essentially ineffective in preschool-aged children with virus-induced wheezing without atopic sensitization whose episodes are less frequent.[137,140] Long-term, sustained corticosteroid therapy has unfortunately had no effect on the course of asthma once the therapy is discontinued.[62]

Early experience with the antiviral substance ribavirin in bronchiolitis suggested that mild subjective benefits and improvement in oxygenation occurred after near-continuous aerosol administration of this compound.[65,173] The degree of improvement in patients treated with ribavirin was minimal and probably occurred because the placebo group received aerosolized water (an irritant to the airway) rather than saline.[127] No study has shown whether the administration of ribavirin could prevent deaths, avoid the need for mechanical ventilation, or

*References 12, 31-33, 48, 102, 156.

shorten the duration of hospital stays.[65,127,173] Ribavirin is essentially not used for RSV infection currently.

Other approaches to therapy for RSV infection include the use of interferon-α,[29] DNase,[119] and nitric oxide.[143] The results of these studies demonstrated no substantial benefit of any of these approaches. Infants with low serum levels of vitamin A[133,149] and vitamin D[10] are more likely to develop RSV lower respiratory tract infection than infants with normal serum levels of these vitamins. However, there is currently no evidence that supplementation with these vitamins during infection has any effect on the outcome of disease. Surfactant[90,187] has been used in very small studies of bronchiolitis or virus-induced wheezing, with positive effects that require confirmation. Several recent studies have evaluated the effect of 3 percent and 5 percent nebulized saline solutions in bronchiolitis. Some studies have demonstrated reduced length of hospitalization in subjects receiving hypertonic saline,[100,112] whereas other studies have not shown any positive effects.[59,81]

RSV-infected infants have elevated levels of cysteinyl leukotrienes in respiratory tract secretions.[189,190] Although initial studies of leukotriene receptor antagonists in RSV infection suggested that the use of these antagonists could reduce the magnitude of respiratory symptoms after RSV bronchiolitis,[3,91] subsequent studies demonstrated no differences in long-term complications.[13] Preparations containing a very high titer of neutralizing antibody against RSV have been tested in the prevention and treatment of RSV infection in high-risk populations. The results of the prophylaxis studies were positive (see later discussion under Prevention). A significant therapeutic effect of these compounds once RSV infection was established could not be identified, however.[110]

Because bronchiolitis is a viral disease, antibiotics are not useful or necessary. In many instances, the radiographic picture suggests pneumonia and the blood leukocyte count is elevated. In these instances, a physician may feel compelled to administer antibiotics. However, bacterial infection of the lung is rare in bronchiolitis even when infiltrates are identified on chest radiographs. In one large study, secondary bacterial infection occurred in no more than 7 (1.2%) of 565 children with RSV infection.[66] In developed countries, bacterial pneumonia does not commonly complicate RSV infection and may be overdiagnosed when bacterial flora are recovered in cultures of tracheal aspirates.[151] For the vast majority of infants, antibiotics need not be prescribed once RSV infection has been diagnosed or can be stopped immediately thereafter. Institution of antibiotics should be considered during the course of therapy when a change in clinical findings suggests the possibility of secondary bacterial infection.

A child with bronchiolitis generally is more comfortable in the supine position with the head end of the crib slightly elevated. Infant seats are used frequently but are not optimal because the child's head tends to fall to the side or forward, which constricts the upper airway. The sitting position also causes a possibly deleterious upward pressure on the diaphragm. The onset of respiratory failure is usually recognized by virtue of reduced inspiratory breath sounds, severe inspiratory retractions, inability to maintain an oxygen saturation of more than 90 percent in 40 percent ambient oxygen, cyanosis in 40 percent oxygen, decreased or absent response to painful stimuli, and a $Paco_2$ rising to 65 mm Hg or higher. Nasotracheal intubation and positive-pressure ventilation, often with neuromuscular blockade, are indicated in these circumstances.[38,138]

PREVENTION

The development of a method to prevent RSV infection is a high priority. The initial adverse experience with formalin-inactivated vaccine (described earlier) unfortunately has nearly prevented further investigation of inactivated vaccines.[93,188] Live, temperature-sensitive vaccines have been developed by adapting RSV to grow at reduced temperatures in cell culture. This attenuated vaccine was designed to grow at the lower temperatures of the upper respiratory tract but be inactive at the higher temperatures in the lung. In initial field trials, the vaccine strain caused febrile respiratory illnesses in seronegative vaccinees but did not replicate adequately in seropositive subjects.[27] Further trials of temperature-sensitive mutant RSV strains as vaccines showed improved immunogenicity and some protection, at least against rechallenge with the vaccine strain. Nasal congestion was noted in some recipients, however, and there is concern that this degree of nasal obstruction could result in apnea in infants.[86] Numerous other vaccine candidates, including RSV nucleic acid vaccines, bovine RSV strains, parainfluenza virus strains bearing RSV antigens, and human RSV strains with gene deletions or given with immunologically active adjuvants, have been developed. Many of them are in early clinical trials, but development of a successful vaccine is not imminent.[24]

In contrast to the largely negative experience with vaccine development, protection against serious illness caused by RSV infection was achieved using a pooled preparation of human serum obtained from donors with very high titers of neutralizing antibody against RSV.[61] This compound, when administered during the RSV season on a monthly basis to infants and young children with a history of birth at less than 32 weeks' gestation or with bronchopulmonary dysplasia, caused a marked reduction in the rate of hospitalization related to RSV infection.

These trials have been repeated successfully using a humanized mouse monoclonal antibody against the RSV fusion protein.[139] The antibody is reconstructed so that it has more than 95 percent of the protein structure of a human antibody. This compound is approximately 50 percent effective in preventing RSV-related hospitalization when administered to high-risk infants, and it has received approval for use in infants born prematurely with or without lung disease of premature birth. Separate trials in infants with hemodynamically significant congenital heart disease have shown a similar

reduction in the rate of hospitalization for RSV-related illness, and the compound is now approved for use in these infants as well.[46]

COMPLICATIONS AND PROGNOSIS

Virtually all cases of bronchiolitis in healthy children resolve without acute complications. Secondary bacterial infection in bronchiolitis now is a rare occurrence, at least in developed countries. Scott and colleagues[162] identified minor electrocardiographic abnormalities in 2 percent of 188 children with bronchiolitis. Involvement of other organs apparently does not occur.

The overall mortality rate in bronchiolitis is low. Before the modern era of improved ventilatory support, mortality rates ranged from 2.0 to 5.5 percent.[33,70,75] A multicenter study in Great Britain published in 1978[154] estimated the mortality rate owing to RSV infection in infancy at 0.5 percent. Deaths should occur rarely except among infants with severe underlying cardiac or pulmonary disease; even in these cases, the mortality rate should not exceed 1 percent of cases.[46] Between 1979 and 1997, an average of 95 bronchiolitis-associated deaths occurred annually in the United States, with 20 percent occurring in infants with underlying heart disease, lung disease, or premature birth.[168]

The possible association of bronchiolitis with the subsequent development of asthma has been debated for decades. Fifty percent of patients with bronchiolitis have recurrent episodes of wheezing, although this figure decreases to approximately 10 percent by adolescence and may not be above that of the general population by this time.[116,117,178] Whether this recurrent wheezing is caused by RSV infection or, alternatively, suggests that RSV infection in early life is an indicator of a tendency toward airway obstruction is still being investigated. Recurrent wheezing after having a case of bronchiolitis could reflect an inherited asthmatic trait. Some studies find a strong correlation between atopic family history and postbronchiolitic wheezing,[41,158,211] whereas others, particularly studies from Great Britain,[147,170,171] do not. Studies of twins born in Denmark suggest that a hereditary predisposition to asthma is more likely to explain the development of bronchiolitis than bronchiolitis is likely to explain the development of asthma.[186] In other studies, titers of total serum IgE[145,177] and peripheral blood eosinophil counts[40,114,211] have some predictive value for the development of recurrent wheezing in infants having had bronchiolitis. Two studies showed that peripheral blood eosinophilia during viral infections, particularly RSV bronchiolitis, predicts the development of recurrent wheezing in school-aged children.[40,114] It has become apparent that rhinovirus-induced bronchiolitis has particular implications for recurrent wheezing in childhood. First, rhinovirus-induced bronchiolitis appears to be more common in infants with atopic dermatitis and eosinophilia than in other infants.[97,99,121] In addition, the occurrence of rhinovirus-induced bronchiolitis in infancy bears a much stronger relationship to the development of wheezing beyond 3 years of age than RSV bronchiolitis, probably because rhinovirus bronchiolitis occurs more frequently in infants predisposed to develop childhood asthma.[82] Atopy seems to explain much, although not all, of the recurrent wheezing that occurs after infantile bronchiolitis.

RSV infection in early infancy could also damage the developing airway, rendering the airway more prone to obstruction in later life. Pulmonary function tests performed in former patients with bronchiolitis 12 years after an episode of bronchiolitis reveal an increased frequency of airway hyperreactivity in response to challenge with exercise or chemical agents, increased ratios of residual volume to total lung capacity, and reduced expiratory airflow at low lung volumes.* Although these abnormalities are observed commonly in individuals with asthma, they could not be explained in several of the previous studies simply by the presence of a personal or family history of atopy.[65,147,180] Some of these retrospective studies showed, however, that a single episode of RSV bronchiolitis was not associated with long-term lung dysfunction; abnormal lung function was observed only if at least two episodes of lower respiratory tract illness had occurred before the patient had reached 2 years of age.[73,191] These studies generally suggest that atopy may explain more of the recurrent wheezing after infantile bronchiolitis than airway damage from the infection itself.

Prospective studies show that recurrent wheezing in children up to age 3 years after bronchiolitis is related to abnormalities of lung function that existed before RSV infection occurred.[113] Wheezing persisting beyond age 3 years was related, at least partially, to the atopic status of the host, as well as a history of asthma in the mother.[22,82,99] No study has shown a relationship between the severity of the initial bronchiolitis episode and the degree of abnormality of long-term lung function.[63,64,147,170] Personal atopy is responsible for many of the long-term manifestations proposed to be sequelae of bronchiolitis. Some factor other than atopy may determine in part the apparent lung abnormalities seen after a case of bronchiolitis,[116,195,207,208] but no direct evidence indicates that this other factor is the initial episode of RSV infection itself.

RSV infection could also account for recurrent wheezing by inducing persistent airway hyperreactivity. Retrospective studies have shown that airway reactivity is, in fact, greater in individuals 1 decade after having an episode of infantile bronchiolitis than in control populations without a history of bronchiolitis.[63,147] Airway reactivity in all children (even children never experiencing bronchiolitis) is greater than that in adults, however, and it is greatest in children of atopic families and in children exposed to cigarette smoke.[209] Airway hyperreactivity occurring after bronchiolitis is, therefore, not necessarily a reflection of the RSV infection itself. One prospective study found no relationship between RSV bronchiolitis and the degree of airway reactivity at age 2 years.[2]

*References 63, 87, 147, 170, 179, 180, 183, 204, 206.

RSV infection possibly can promote sensitization to allergens. In animal models, critically timed RSV infection can enhance temporarily the degree of airway reactivity induced after sensitization to an allergen. Whether this phenomenon occurs in humans is unknown. The absence of Th2-like cytokine responses at the time of having RSV bronchiolitis[54] suggests, however, that RSV infection in infancy likely does not promote a persistent atopic state in the host. The results of a recent, large European study (ALSPAC) showed that hospitalization in infancy for RSV bronchiolitis was associated with subsequent childhood wheezing and asthma but not atopy.[74]

RSV infection more likely results in the release of mediators of airway obstruction, such as histamine and leukotrienes, through a mechanism other than Th2 cytokine responses. Chemokines such as MIP-1α, which cause mast cell and basophil degranulation, are possible candidates. Release of these mediators at the time of having RSV infection may result in wheezing in susceptible individuals. These same individuals may develop wheezing again at the time of having allergen exposure in childhood (particularly if they are atopic), but the relationship of bronchiolitis in infancy and such subsequent childhood wheezing would not be causal. Rather the association would be based on the underlying susceptibility of the airway to obstruction.

The overall outlook for infantile bronchiolitis generally is excellent. In a follow-up study conducted at the Women & Children's Hospital of Buffalo,[195] severe lung disease was not observed in former bronchiolitis patients. All oxygen saturation levels were greater than 95 percent, and at least some of the airflow obstruction present in patients aged 7 to 9 years was reversible with a single bronchodilator treatment, as was confirmed later.[176] Single episodes of infantile bronchiolitis (in the absence of passive smoke exposure and without recurrent wheezing episodes) have not been associated with abnormalities of lung function or airway hyperreactivity in later childhood.[87,180,191]

The natural history of postbronchiolitic wheezing in childhood is for episodes of wheezing to become progressively milder,[63,117,147,170] and the frequency of postbronchiolitic wheezing apparently eventually decreases to essentially the same rate as that of children who did not experience bronchiolitis in infancy.[73,117,176] Nonetheless, the overall prognosis is not entirely benign, and exposure to noxious environmental elements may result in an accelerated deterioration of lung function in later life.[29,202,206] The combination of respiratory tract illness in early life and subsequent cigarette smoking especially may be harmful.[181] Individuals who develop bronchiolitis in infancy should avoid smoking in later life and occupations that are associated with exposure to respiratory irritants.

CHAPTER 22

Pediatric Community-Acquired Pneumonia

Carrie L. Byington • John S. Bradley

Community-acquired pneumonia (CAP) is the most important cause of death in children worldwide.[157] The World Health Organization estimates 1.4 million deaths in children younger than 5 years occur each year, accounting for almost 1 in every 5 deaths in this age group.[167] This number of deaths exceeds that of acquired immunodeficiency syndrome (AIDS), malaria, and tuberculosis combined. In the developed world, CAP results in hundreds of thousands of medical encounters and hospitalizations. In the United States, influenza and pneumonia remain an important cause of death, accounting for more than 50,000 deaths in 2010, including several hundred deaths in children.[125]

CAP is an acute lung infection that results most commonly from viral or bacterial pathogens. Less typical pathogens, including mycobacteria and fungi, also may cause pneumonia, especially in immunocompromised hosts. These infections are discussed in detail in Chapter 97 and the chapters discussing fungal infections.

In the United States, the Pediatric Infectious Diseases Society (PIDS) in collaboration with the Infectious Disease Society of America (IDSA), published guidelines in 2011 for management of CAP in infants and children older than 3 months.[26] These guidelines define CAP as the presence of signs and symptoms of pneumonia in a previously healthy child caused by an infection acquired outside of the hospital.[26] The diagnostic, management, and prevention strategies discussed in this chapter are aligned with these published guidelines.

ETIOLOGY

Because of the difficulty of documenting the microbiology of pneumonia in infants and young children, accurate data concerning the incidence and specific agents of bacterial and viral pneumonia in children are lacking. Although up to a third of CAP is thought to be due to bacterial pathogens, nonbacterial pneumonias remain the most frequent pulmonary infections encountered in pediatrics. Etiologic studies conducted between the 1970s and 1990s indicated that two bacterial pathogens were responsible for the majority of fatal cases of childhood pneumonia—*Streptococcus pneumoniae* and *Haemophilus influenzae* type b.[64,102] In the intervening years, effective protein conjugate vaccines (PCVs) that protect against *H. influenzae* type b and *S. pneumoniae* have been introduced into the vaccine programs of many countries, including the United States. In addition, diagnostic technology has advanced and molecular testing for bacterial and viral pathogens is changing our understanding of the etiology of childhood pneumonia.

Two large studies are currently underway to better document the etiology of childhood pneumonia. In the United States, the Centers for Disease Control and Prevention (CDC) is conducting the Etiology of Pneumonia in the Community (EPIC) study. It is a multicenter study with enrollment of children in Tennessee and Utah. The study participants are children younger than 18 years who are hospitalized with pneumonia and are evaluated using conventional microbiologic methods, serology, and molecular diagnostics for viral and bacterial pathogens. Preliminary data indicate that viral pathogens are the most common pathogens in children with hospitalized CAP, identified in approximately 75 percent of cases.[81] Of viral pathogens, rhinovirus is most commonly detected, identified in 37 percent of children as a single pathogen or copathogen. Children with CAP and rhinovirus have higher viral loads than healthy children with rhinovirus, although the interpretation of a positive rhinovirus test in children with CAP is evolving.[146] Respiratory syncytial virus (RSV) is the next most commonly detected, identified in 25 percent of children, usually as a sole pathogen. Other important viruses include adenovirus detected in approximately 15 percent of hospitalized cases, human metapneumovirus (hMPV) and parainfluenza detected in about 10 percent of cases, and coronaviruses and influenza viruses, detected in around 5 percent of children with hospitalized CAP.[81] Bacterial infections are less common, identified in 12 percent of children hospitalized with CAP.[81] When bacterial pathogens are recovered through culture or polymerase chain reaction (PCR) of blood or pleural fluid, *S. pneumoniae* and group A streptococcus are important bacterial causes of CAP in children, particularly CAP complicated by empyema.[9] *H. influenzae* type b was only rarely identified, although the majority of children were immunized. In addition, viral pathogens including rhinovirus, RSV, adenovirus, hMPV, coronaviruses, and influenza A and B are often identified in combination with bacteria in children hospitalized with CAP.[9]

Internationally, the Bill and Melinda Gates Foundation is sponsoring the Pneumonia Etiology Research for Child Health (PERCH) project. This case-control study involves seven countries in two geographic regions, Africa and Asia, where most cases of fatal childhood pneumonia

occur. PERCH sites include Bangladesh, Gambia, Kenya, Mali, South Africa, Thailand, and Zambia.[102] The study evaluated children 1 to 59 months and uses conventional and molecular methods to identify an etiology for pneumonia. Preliminary data from Kenya demonstrate an etiology in more than 75 percent of cases, with bacteria identified in 9 percent (most commonly *S. pneumoniae*), viruses in 53 percent, and mixed viral and bacterial infection in 15 percent.[74] An additional pilot study conducted in New Caledonia as part of the PERCH trial identified a pathogen in 89 percent of 108 hospitalized cases, with viruses representing more than 80 percent of the pathogens detected, similar to the findings of the EPIC study in the United States.[117]

Viral Pathogen

Of the viral pathogens, RSV generally is accepted as the agent found most frequently in pediatric pneumonias, particularly those associated with bronchiolitis. Although infection with this virus is quite common in all age groups, lower respiratory tract involvement is especially prominent in infancy.

hMPV, a newly identified paramyxovirus, was first described in children with upper and lower respiratory tract infection in the Netherlands in 2001.[153] Nearly 100 percent of children have serologic evidence of hMPV infection by age 5 years approximately 5 to 10 percent of children with CAP.[103,163,165] The clinical symptoms in infected children resemble those caused by RSV and influenza and may result in severe pneumonia.[153] A study conducted in Utah from 2006 to 2011 noted that the incidence of hospitalization for hMPV was highest in infants younger than 1 year of age (238/100,000) and lowest among children 5 to 17 years of age (6/100,000); 14 percent required intensive care admission, and 5 percent required mechanical ventilation.[47]

The three parainfluenza viruses (types 1, 2, and 3) are also commonly identified as pathogens in lower respiratory tract disease in infants and younger children. Parainfluenza virus type 3 is the agent most frequently found in pneumonia[67,68] and has been reported as an important pathogen with significant mortality in pediatric cancer patients with lower respiratory tract infection.[108]

Influenza A and B viruses are not as prevalent overall as RSV and parainfluenza viruses, but during periods of epidemic or pandemic spread, they may become predominant isolates in children with lower respiratory tract disease.[14,57] Infection with influenza viruses predisposes children to bacterial pneumonia and empyema, particularly as a result of *S. pneumoniae* and *Staphylococcus aureus*.* The threat of a pandemic of virulent influenza A, secondary to a recombination event resulting in a "human-adapted" avian or swine flu virus, keeps influenza in the forefront of concern for global public health agencies.[66]

Adenoviruses commonly are detected in children with CAP, particularly those who are hospitalized.[27,81,95] The overall impact of these viruses in the origin of nonbacterial pneumonia in children probably is somewhat less than that of the aforementioned agents; however, many fatal illnesses have been reported. Their common asymptomatic carriage and potential for endogenous activation by unrelated illnesses can render causation difficult to prove.[62] Of the 51 known adenoviruses, types 1, 2, 3, 4, 5, 7, 14, 21, and 35 clearly have been associated with pneumonia.[27,87] In certain populations, such as the Maori, Native Americans, and Inuit, adenoviruses commonly produce severe infection.[78,91] Adenovirus infections also have been reported in military recruits, some with fatal outcomes.[31,41,152,155]

Evidence to support the role of rhinoviruses in pneumonia is increasing, although upper respiratory tract infection with the multiple serotypes of these organisms is common. Some degree of lower respiratory tract involvement by rhinoviruses is indicated by the documented role of these viruses in bronchiolitis and exacerbations of asthma.[82] Rhinovirus C has been implicated in severe pneumonia in children and neonates.[30,38,92]

Coronaviruses HCo-OC43 and HCo-229E have been implicated as causes of pneumonia since the 1960s, but until recently, this family of viruses was considered a rare cause of human disease.[86,115] The worldwide epidemic of severe acute respiratory syndrome (SARS) that occurred in 2002 to 2004 focused new interest on these pathogens and led to a new appreciation of their reservoirs in domestic animals and their potential to cause severe pneumonia and respiratory failure.* Two other strains of coronavirus, HCo-NL63[154] and HCo-HKU1,[166] have been discovered more recently. They appear to be among the less common causes of lower respiratory tract infections, but their clinical manifestations are similar to those caused by the other common respiratory viruses.[55,135]

The respiratory virus most recently described that can cause pneumonia is HBoV.[4] It is a parvovirus closely related to bovine parvovirus and canine parvovirus. (The "bo" in "bocavirus" derives from "bovine" and the "ca" from canine.) It was identified using a novel technique based on amplification of nonspecific viral nucleotide sequences, a method that holds promise for identification of other previously uncultivated human viral pathogens. Because only a few population-based studies have been performed, the contribution of HBoV to the overall epidemiology of pediatric pneumonia remains uncertain. HBoV has been identified in respiratory specimens, including sputum and bronchoalveolar lavage in children with acute respiratory tract infection,[19,26,76,123] and was found to be a relatively common (19%) finding in a Finnish study of children with asthma exacerbations.[3] However, with bocavirus being detected far more often with another viral pathogen, rather than as a sole agent,[55] with documentation of asymptomatic respiratory tract "colonization" with bocavirus,[111] and prolonged excretion even after symptoms have resolved, it is difficult to accurately assess bocavirus-attributable lower respiratory tract morbidity.

Bacterial Pathogens

S. pneumoniae remains an important cause of bacterial CAP in children beyond the neonatal period in both

immunized and unimmunized populations. In immunized populations, the serotype distribution changed significantly after the introduction of pneumococcal PCVs. After the introduction of the PCV7 in the United States, serotypes 3, 7F, and 19A emerged as important causes of CAP and complicated pneumonia.* Worldwide, serotype 1 also is often associated with complicated pneumonia.[20,36,54,129,131] These serotypes are included in the PCV13 formulation, and in 2010, the first year after introduction of PCV13 in the United States, further decreases in invasive pneumococcal disease, including pneumonia, have been reported.[42,44]

The availability of molecular diagnostics is changing our understanding of CAP and demonstrating the presence of both viral and bacterial pathogens in children with pneumonia is common.[23,72] Further, the developing immune system from the newborn to adolescent and immunization status of children also influences the pathogens responsible for CAP in different age groups. Table 22-1 provides information regarding common pathogens seen in CAP in different age groups. Knowledge of regional data regarding pneumonia etiology, particularly the likelihood of drug-resistant pneumococci and methicillin-resistant *S. aureus* (MRSA), is vital for decision making regarding diagnostic testing and treatment.

EPIDEMIOLOGY

In the developed world, CAP remains a common cause of pediatric hospitalization and ambulatory medical visits. Age is an important determinant of disease rates, with younger children more likely to have CAP and be hospitalized. In the United States, hospitalization rates for CAP ranged from a high of 1169/100,000 for infants younger than 1 year to a low of 44.7/100,000 for children 13 to 18 years of age.[94] Children 1 to 5 years had rates of 383/100,000 and those 6 to 12 years had rates of 69/100,000.[94] Race is also an important factor in CAP. Black children have higher rates of hospitalization for CAP in contrast to white children; however, the difference has decreased since the introduction of pneumococcal conjugate vaccines.[94] Immune status is also relevant when identifying risk for CAP. Children with congenital and acquired immune deficiency, including human immunodeficiency virus (HIV) infection, are at increased risk for lower respiratory tract infection caused by both common[7,127] and uncommon respiratory pathogens, which are described in more detail in the chapters on immunocompromised hosts.

The epidemiology of CAP in the United States changed significantly after the licensure of the *H. influenzae* type b and pneumococcal conjugate vaccines. Overall, rates of invasive pneumonia have decreased in children younger than 5 years, the age group targeted for pneumococcal conjugate vaccines.[132] Decreases also have been observed in adults and suggest a likely benefit from herd immunity.[132]

PATHOGENESIS

The pathogenesis and host immune response differs significantly among viral, bacterial, and mycoplasma pathogens.[65,138,156] Detailed information regarding pathogen-specific disease can be found in chapters describing each pathogen.

For viral pneumonia, the pathological processes associated with infection by RSV, adenoviruses, and influenza virus A have been studied most extensively in humans, aided by animal models for each pathogen.[49] For most viral lower respiratory tract pathogens, inoculation of the child starts with the upper respiratory tract after exposure to infectious secretions from others through sneezing or coughing or from fomites. Once in the lower respiratory tract, viral agents proliferate and spread by contiguity to involve the lower and more distal portions of the respiratory tract. Infected epithelium loses ciliary function, rounds up as a result of injury, and sloughs into the air passages, with subsequent stasis of mucus and accumulation of cellular and inflammatory debris. When infection

*References 17, 35, 36, 46, 69, 79.

extends to the terminal airways, alveolar lining cells themselves will lose structural integrity and function. As a result, surfactant production may be lost, hyaline membranes form, and pulmonary edema may develop. Mononuclear cells infiltrate submucosal and interstitial structures, further contributing to tissue edema, narrowing of air passages, and alveolar-capillary block of gas exchange.[83] With certain pathogens, particularly RSV, bronchiolar spasm in the context of accumulating airway debris gives rise to ball-valve–mediated air trapping with each inspiration, resulting in hyperinflation. Complete obstruction of an airway by debris may result in distal atelectasis. Ventilation-perfusion mismatch may add to hypoxemia that results from alveolar edema.

Histopathologic descriptions of the viral pathology can include acute bronchiolitis, necrotizing bronchiolitis, interstitial pneumonia, alveolar pneumonia, and hemorrhagic bronchopneumonia. Acute bronchiolitis is characterized by relatively superficial and reversible destruction of ciliated respiratory epithelium, along with accompanying mononuclear infiltration in submucosal tissues. Necrotizing bronchiolitis extends to the deeper submucosal layers lining the respiratory tract and may not be as readily reversible. This destructive pathology is associated particularly with adenoviral pneumonia.[130]

Interstitial pneumonia is a diffuse process in which the inflammatory mononuclear response predominantly involves the peribronchial alveolar septa. In alveolar pneumonia, the alveoli are filled with degenerating lining cells and mononuclear or polymorphonuclear inflammatory cells with or without hyaline membranes and may reflect bacterial superinfection, acute respiratory distress syndrome, or nonspecific changes associated with mechanical ventilation and oxygen toxicity. Hemorrhagic bronchopneumonia has been described in a fatal pediatric case of hMPV lower respiratory tract infection.[51] When hyaline membranes are present, the process is described as diffuse alveolar damage, the histopathologic hallmark of acute respiratory distress syndrome. Acute bronchiolitis and interstitial pneumonia have classically been observed in most cases of fatal viral pneumonia, regardless of the infecting pathogen.[1]

Both viral replication and age-specific immune responses contribute to the severity of RSV disease in infants. It appears that the severity of RSV in infants relates to a vigorous innate immune response and inadequate adaptive immune response to viral replication and destruction of the respiratory tract epithelium. RSV infection initiates tremendous innate inflammation through both chemokines and cytokines, after stimulation of airway epithelial cells and phagocytic cells, as reviewed recently.[161,162]

Three important factors that influence the pathologic expression of nonbacterial pneumonia in children are anatomy, preexisting pulmonary disease, and immunity. In young infants, the small caliber of the terminal airways and the absence of interconnections between alveolar spaces (pores of Kohn) contribute to the development of wheezing and lobular atelectasis.[164] Preexisting pulmonary disease (e.g., bronchopulmonary dysplasia) and an inability to clear the excessive secretions triggered by infection in patients with bronchopulmonary dysplasia also may lead to bronchospasm, atelectasis, and respiratory failure.

The most important factors in the pathogenesis of bacterial pneumonias are the virulence of the pathogen, the absence of specific humoral immunity, and the presence of a preceding viral respiratory tract infection. Most bacterial pneumonias are a result of colonization of the nasopharynx, followed by either bacteremia or aspiration of organisms. The lung is protected from bacterial infection by a variety of mechanisms, including entrapment and removal of organisms deposited on airways by ciliated epithelium and mucus, ingestion and killing of airway bacteria by alveolar macrophages, by reticuloendothelial system function for organisms gaining access to the lung via the bloodstream, by neutralization of invading bacteria by local and systemic nonspecific innate and specific immune substances (i.e., specific antibody, complement, opsonins), and by removal of invading organisms from the lung by lymphatic drainage. Pulmonary infection may occur when one or more of these barriers are altered, inhibited, or overwhelmed.

Animal models document that the inflammatory responses in the lung may be caused by various bacterial cell wall components, including peptidoglycans, lipoteichoic acid (of gram-positive organisms), and lipopolysaccharides (endotoxin) of gram-negative bacteria. Bacterial components stimulate a profound innate inflammatory response, initiated in part by activation of pattern-recognition receptors (most notably Toll-like receptors [TLRs]), followed by an intense inflammatory cascade mediated by cytokines and chemokines that results in upregulation of cell surface adhesion molecules in addition to multiple intracellular pathways.[37,65]

As classically described, pneumonia caused by *S. pneumoniae* begins with acute inflammation and hyperemia of the lower respiratory tract mucosa, exudation of edema fluid, deposition of fibrin, and infiltration of alveoli by polymorphonuclear leukocytes (i.e., "red hepatization"), followed by predominance of fibrin deposition and macrophage activity (i.e., "white hepatization"). Resolution subsequently occurs with absorption of exudates and return of lung morphology and physiology to normal. In contrast, when the pneumonia is caused by organisms capable of inciting even more profound tissue inflammation (e.g., *S. aureus*, gram-negative enteric bacilli or pseudomonads), destruction of tissue, and formation of abscesses frequently occur.

Recent animal data provide a scientific basis for the observation that signs and symptoms of a viral respiratory tract infection frequently precede development of bacterial pneumonia. The respiratory virus may act by both destruction of respiratory epithelium and upregulation of functional bacterial cell surface antigen receptor molecules.[112,113] Staphylococcal or pneumococcal pneumonia may occur during or shortly after infection caused by influenza virus. Severe pneumococcal pneumonia has been associated with outbreaks of influenza, and increased mortality rates from pneumonia occur during epidemics of influenza, as documented from new postmortem studies of fatalities during the influenza pandemic of 1918.[119,143] As indirect proof of the role of preceding viral infection, the use of conjugate pneumococcal vaccines

appears to have decreased some of the lower respiratory tract morbidity seen with influenza infection.[88] Further, the conjugate vaccines were shown to reduce chest radiograph–defined alveolar consolidation associated with RSV by 12 percent, with parainfluenza types 1 to 3 by 44 percent, and with hMPV by 40 percent, suggesting that concurrent pneumococcal infection was frequent in virus-associated pneumonias. By documenting the decrease of bacterial pneumonia in immunized patients, the conjugate pneumococcal vaccine has been valuable in identifying the role of viral and pneumococcal coinfection.[106,107] Immune compromise, anatomic defects, and neurologic comorbidities may predispose children to recurrent lower respiratory tract infection, but a detailed discussion of these risk factors is beyond the scope of this chapter.

Mycoplasma is primarily a mucosal pathogen, attaching extracellularly to the epithelial cells of the host airways. Attachment leads to the generation of an inflammatory response with production of cytokines with subsequent recruitment of lymphocytes and neutrophils to the airway mucosa, leading to the production of inflammatory infiltrates within the airways. *Mycoplasma* attaches to airway cells by means of unique attachment organelles, resulting in cytopathic effects on ciliated epithelium of bronchi and bronchioles that can include loss of cilia, vacuolization, loss of metabolic function, and ultimately cell death. Edema with bronchiolar and alveolar inflammatory infiltrates containing macrophages, lymphocytes, neutrophils, plasma cells have been described. Diffuse alveolar damage also has been reported.[16]

The nonpermanent immunity that develops with natural infection provides a vigorous cell-mediated immune response that, on reexposure to *Mycoplasma*, may lead to more severe clinical illness and pulmonary injury. This concept of immune-mediated lung disease provides the basis for increasing pulmonary disease severity with increasing age, which correlates with observed, specific cell-mediated immunity that also increases with age.[12,96]

CLINICAL MANIFESTATIONS

The clinical presentation of a child with pneumonia is most often based on symptoms directly related to decreased oxygenation of blood (hypoxemia), as well as symptoms directly related to lung inflammation, characteristically caused by a pathogen in a particular age group (from very young infants to adolescents). A benign viral lower respiratory tract infection caused by rhinovirus may produce only a cough, with no tachypnea, or clinical toxicity. In contrast, a bacterial pneumonia caused by MRSA, may result in tachypnea, dyspnea with grunting respirations and retractions, cyanosis, high fever, hypotension, and altered mental status. Detailed, pathogen-specific clinical presentations are provided within the chapters discussing each pathogen.

Of importance is the recent recognition of the high frequency of coinfections caused by both a virus and bacteria or caused by multiple viruses. In these situations, the clinical presentation and progression of disease may be an amalgamation of two or more pathogens. The association of influenza virus infection with subsequent bacterial pneumonia is perhaps the best studied. In these situations, the first signs of infection are those of viral disease, with coryza and sore throat, but subsequently develop into respiratory failure that is associated with consolidative pneumonia or necrotizing pneumonia that is characteristic of *S. pneumoniae* or *S. aureus*.

Clinical manifestations of hypoxemia in children may occur after infection by either viruses or bacteria. Although these clinical presentations have been best studied in the developing world, the pathogens responsible for lower respiratory tract infection, particularly bacterial pathogens, are seldom identified in these studies, making pathogen-specific descriptions of disease presentation or clinical course difficult. Regardless of pathogen, however, those with more severe hypoxemia will have various degrees of respiratory distress (Table 22-2).

Whereas the older child and adolescent can verbalize the sensation of dyspnea, the younger child or infant may present with hypoxemia with increased respiratory effort and decreased level of attentiveness, decreased consolability, poor color, and decreased spontaneous movement, which has been best described in young infants with bronchiolitis.[110] In resource-poor areas of the world, cyanosis has been documented to be associated with severe hypoxia. A systematic review of published studies, primarily in the developing world, found that cyanosis and use of accessory muscles associated with the head tilting downward with each inspiration had a higher specificity for predicting hypoxemia in children than other signs, but were not sufficiently sensitive to be able to be used in the clinical diagnosis of hypoxemia.[13]

Tachypnea is a nonspecific clinical sign that may be a result of fever, anxiety, metabolic acidosis, or the hypoxemia that accompanies respiratory failure. Whereas in the developing world, rapid breathing as perceived by the mother, as well as chest retractions, nasal flaring, and crepitations were statistically associated with hypoxemia, the sensitivity and specificity of tachypnea in diagnosing hypoxemia were both only about 70 to 75 percent in contrast to that of pulse oximetry.[105] Likewise, in a recent study from a pediatric emergency department in Boston of children younger than 5 years of age undergoing chest radiography for possible pneumonia, the respiratory rates

TABLE 22-2 **Criteria for Respiratory Distress**

7. Altered mental status
8. Pulse oximetry <90% on room air

*Adapted from World Health Organization criteria.

for those with documented pneumonia by chest radiograph were not statistically higher than those whose chest radiographs were normal.[140] However, in the developing world, a high, age-specific respiratory rate (tachypnea), particularly when measured at 24 hours into antimicrobial therapy (amoxicillin or penicillin G), has been linked to clinical treatment failure in children with severe pneumonia.[109]

In the developed world, realizing that clinical presentation of pneumonia is neither sensitive nor specific for the diagnosis, pulse oximetry is widely used as the basis for management decisions, to confirm clinical suspicions of pneumonia with hypoxemia. Pulse oximetry technology is widely available, accurate in most settings, and simple to perform and has the ability to quantitate the severity of lung disease. Hypoxemia is a risk factor for poor outcome in both adults and children with lower respiratory tract infection. Although pulse oximetry is used together with clinical assessment, recommendations have been made to hospitalize a child whose Spo_2 is less than 90 percent in room air, although prospectively collected data to assess the risks and benefits of this particular value have not been studied in the developed world.[26,63] Given the lack of scientific data to support specific Spo_2-based recommendations, it is understandable that some practice variation exists.[32]

Viral pathogens are far more commonly associated with lower respiratory tract infection, particularly for preschool-aged children. The clinical presentation generally follows a short upper respiratory tract infection prodrome (coryza, pharyngitis, mild fever) by a few days, with a gradual onset of cough, usually nonproductive. Clinical toxicity is usually mild for most viral pathogens. Some degree of bronchiolitis may occur with lower respiratory tract infection, leading to wheezing with difficult air entry and prolonged expiration with air trapping within the distal airways (primarily caused by RSV, hMPV, and rhinovirus). Lower respiratory tract disease is most often bilateral, affecting all lobes, in contrast to the more common presentation of focal, unilateral pneumonia caused by bacteria. Disease is usually benign, lasting only 3 to 5 days and resolving spontaneously. With young infants under 1 year of age, particularly those infected by RSV, increasing lung parenchymal inflammation can lead to decreasing oxygenation and respiratory failure. Hypoxemia and significant reactive airway disease may occur, not uncommonly leading to hospitalization. For the most common viral pathogens responsible for clinically significant lower respiratory tract disease, respiratory failure that leads to intubation is extremely unusual but may occur with influenza A or B viruses, particularly in children with comorbid medical conditions. Very uncommon viral pathogens, including SARS coronavirus and influenza H5N1 (avian influenza) may cause rapidly progressive respiratory failure with a high mortality rate.

In contrast, bacterial pneumonia may have a more rapid progression from cough to dyspnea, and is more often associated with signs and symptoms of systemic toxicity, including high fever, hypotension, myalgias, malaise, headache, gastrointestinal complaints, restlessness, apprehension, and, on occasion, manifestations of secondary sites of infection. As with viral disease, signs and symptoms of bacterial pneumonia vary with the bacterial pathogen and the age of the child. Pleural fluid collections, which may be extensive, can become infected, resulting in bacterial empyema that is a well-recognized complication of bacterial CAP. Some bacteria are associated with a specific pattern of disease, such as the lobar pneumonia of *S. pneumoniae* and the empyema, abscess, and pneumatocele formation caused by *S. aureus;* however, any of these manifestations may result from infection caused by any of the bacterial pathogens. In general, children with bacterial pneumonia have cough, tachypnea, and, with progressive disease, symptoms that are characteristic of hypoxemia, including dyspnea, shallow or grunting respirations, and flaring of the alae nasae. For lower lobe pneumonia, inflammation may be associated with gastrointestinal symptoms, including abdominal pain that may mimic that of appendicitis. Signs of pneumonia may be subtle in young infants. Percussion usually is not valuable in an infant or older child if distribution of the pneumonia is patchy. Dullness to percussion is associated more often in young children with the presence of pleural fluid than with the involvement of the parenchyma of the lung. Auscultatory findings classically include rales, or, for the child with consolidation, "tubular" breath sounds not associated with rales, lacking the normal breath sounds associated with gradual aeration and expansion of the lung with each inspiration. Abnormal findings in older children include dullness to percussion, decreased tactile and vocal fremitus on palpation, and the presence of egophony. Intercostal retraction indicates recruitment of accessory muscles, often necessary to assist respiration when hypoxemia is present.

Irritation of the pleura and accumulation of pleural fluid is accompanied by chest pain that may be severe and may limit chest movement. As the effusion enlarges, dyspnea may increase, but pleuritic pain may diminish and become a dull ache. The pain of pleural irritation may be present at the site of inflammation or may be referred. Pleural irritation over the right upper lobe may elicit meningismus, a sign of meningeal irritation.

Atypical pneumonia in children is most often caused by *Mycoplasma pneumoniae;* disease caused by either *Legionella pneumophila* or *Chlamydophila pneumoniae* is quite rare.[26] Unfortunately, no prospective natural history studies that involve routine screening of both outpatients and inpatients for *Mycoplasma* spp. infection in all pediatric age groups have been performed. Most studies of CAP in children that collected clinical information on *Mycoplasma* were retrospective, including some reporting outbreaks. Some reported data in children are derived from prospective antimicrobial therapy studies for adults, with insufficient numbers of evaluable children to allow a basic understanding of the disease in children.[122,145] *Mycoplasma* spp. clinical presentation is indistinguishable from that of viral pneumonia, prompting recommendations to clinicians to test for *Mycoplasma* before starting antimicrobial therapy. Presenting complaints are generally related to slowly progressive systemic symptoms over 3 to 7 days, with malaise, pharyngitis, and headache, followed by cough.[12,156] Cough usually is irritative and nonproductive, reflecting tracheobronchitis, a manifestation

of cell injury and host response to lung inflammation, which rarely progresses in children to hypoxemia requiring hospitalization and supplemental oxygen. Cough may last for 2 to 4 weeks or longer and is associated with clinical findings of rales, rhonchi, and wheezes that may be so prominent in the context of a child who does not appear ill as to merit the common name of "walking pneumonia." Similar to certain viral pathogens, *Mycoplasma* may be associated with increased wheezing in children with asthma, particularly younger infants. The clinical presentation in preschool children is generally less severe than in older children, presumably as a result of less immune-mediated inflammation. Those under 5 years of age are less likely to have disease with a lobar pattern on chest radiography.[96]

DIAGNOSIS

Diagnostic testing for CAP is summarized in this section and reviewed in detail in the 2011 IDSA and PIDS guidelines.[26] In children who are immunized against common bacterial causes of CAP, including *H. influenzae* type b and pneumococcus, and who do not require admission, limited diagnostic testing is recommended. Pulse oximetry is recommended to identify children with hypoxemia who may require additional testing or admission. In children who do not have hypoxemia, history and physical examination are sufficient to identify signs and symptoms of pneumonia and confirmation by chest radiography is not required at the initial visit. In children who are younger than 5 years, the majority of CAP will be due to viral pathogens and no antibiotic treatment is indicated. In children who have a worsening course with or without antibiotic therapy, a chest radiograph to evaluate the extent of infiltrate and to identify the presence or absence of pleural fluid should be obtained. Similarly, blood culture and complete blood count rarely change the treatment course in children who are managed as outpatients and are not recommended.[19,22,77,141] Testing for viral pathogens in the outpatient setting is increasingly possible. Viral testing may identify children with RSV who are at low risk for secondary bacterial pneumonia and may identify children with influenza who would benefit from antiviral therapy. Antiviral therapy for influenza should be administered to all children with influenza-like illness who are also at high risk for complications during periods of influenza circulation in the community, even if rapid antigen-based influenza testing is negative, because these tests lack high sensitivity.[6,8]

For children who require hospitalization, blood cultures are positive in approximately 1 to 11 percent of children and are recommended. When positive, blood culture results can guide definitive antibiotic treatment. Complete blood count may be useful in hospitalized children to identify anemia and thrombocytopenia associated with hemolytic uremic syndrome, a rare complication of bacterial pneumonia.[15,28,46,159] Sputum for Gram stain and culture is recommended in adults, but rarely performed in children. For older children and adolescents with severe CAP, sputum testing should be attempted. Urinary antigen tests for pneumococcus are not recommended for children with CAP, because false positive results are common.[126] The use of pneumococcal antigen testing for pleural fluid specimens, however, has been demonstrated to be reliable and improves the identification of a specific etiology for empyema (see Chapter 24).[133]

M. pneumoniae is a common cause of CAP, particularly in children aged 10 to 17 years. The role of diagnostic testing for *M. pneumoniae* is not well defined because limited studies have been conducted on the natural history of *M. pneumoniae* infection and the impact of antibiotic treatment, particularly in young children.[26] Testing may be most useful in school-aged children to guide antibiotic therapy. A variety of diagnostic tests are available. Traditional culture for *M. pneumoniae* is impractical for most clinical laboratories, given the slow growth and complex nutritional requirements of the organism. Cold-agglutinin titers greater than 1:64 are common in adults, but it is unclear how often this occurs in children. In addition, infections with other organisms may cause increases in cold-agglutinin titers, limiting the utility of this diagnostic test. Serologic diagnosis is most often used by clinical laboratories. Several serologic tests are available, including a rapid test for *M. pneumoniae* immunoglobulin (IgM), with sensitivity in published studies ranging from 74 to 96 percent and specificities ranging from 85 to 98 percent.[2,53,149,158] PCR technology is currently used in research settings, but is not widely available for clinical use. Interpretation of positive results, including the duration of positivity, from a variety of specimens such as nasal wash fluid, throat swab, sputum, and pleural fluid will all require further validation before clinical implementation of PCR can be realized.[150,169]

Pathogen-specific diagnoses for bacterial CAP remain challenging, although considerable progress has been made in the identification of pathogens through molecular testing of respiratory specimens. Both the PERCH and EPIC studies described previously use conventional and molecular diagnostics for viral and bacterial pathogens. A combination of these techniques identifies a viral or bacterial pathogen in 75 to 80 percent of hospitalized cases. Nucleic acid amplification also has been useful in identifying pathogens in culture-negative empyema.[20,54,93,124,128] The available methods and reagents are expanding rapidly and include fluorescent antibody techniques, enzyme-linked immunosorbent assay, direct DNA probes, and PCR. Clinical specimens may be tested directly or after preincubation in tissue culture systems.

MANAGEMENT

Management of children with pneumonia in clinics, hospital wards, or intensive care units is based on the severity of the disease. Although severity is clearly associated with certain pathogens, significant overlap exists between the disease caused by bacterial, viral, and atypical pathogens, leading to initial management based on clinical toxicity and degree of respiratory compromise. For this discussion, management is based on access to resources available in the developed world. Significant morbidity and

mortality occur in the developing world; the clinical manifestations of disease may reflect comorbidities and access to health care, and management decisions may depend on the resources available. The history, presentation, and examination of the child determine the severity of the illness and the appropriate level of care with respect to outpatient or inpatient management. The clinician's assessment of the child's respiratory status at the time of the medical encounter and the anticipated clinical course on antimicrobial therapy should determine whether hospitalization is necessary. Decision making should be based on clinical examination and pulse oximetry, supported by chest radiography and laboratory studies.

Any infant or child with respiratory distress (see Table 22-2) will demonstrate some degree of clinical toxicity, and most experts and professional societies recommend hospitalization for the "toxic" child. Although hospitalization in this setting is reasonable and represents the standard of care in the developed world, no prospective, controlled studies have been published that have quantified the degree of improved clinical outcome that results from hospitalization over management in the home.

Clinical decision rules based on initial scoring systems that incorporate a combination of clinical, laboratory, and radiographic findings have not been well defined for children as they have been for adults.[59,121] As previously noted, pulse oximetry represents a direct, simple, and widely available assessment for evaluating the degree of compromise of lower respiratory tract function. Clinical scores for critically ill children that currently exist may help determine whether a child should be hospitalized on a pediatric ward or be admitted to a pediatric intensive care unit. Severity of illness scores built on multiple logistic regression models, such as the Pediatric Logistic Organ Dysfunction (PELOD) score,[100] the Pediatric Risk of Mortality (PRISM) score,[137] and the Pediatric Index of Mortality (PIM),[90] predict the risk for death for children admitted to a pediatric intensive care unit, including those admitted with pneumonia.

Young age (<6 months) presents additional concerns, with some degree of immunocompromise compared with school-aged children and a more compliant chest wall that impairs deep breathing and coughing as mechanisms to help clear pulmonary secretions. In the developed world, very young infants (up to 3 months of age) with pneumonia are generally admitted to the hospital for initial management. Given the increased risks for morbidity for children under 1 year of age, recommendations for hospitalization of infants up to 6 months of age with suspected bacterial pneumonia also have been made.[80,139]

The presence of important comorbidities, including reactive airway disease, genetic syndromes, neurocognitive disorders, immune compromise, and chronic cardiac and pulmonary conditions are also risk factors for the pneumonia requiring hospitalization.[118,147] Children with a comorbid condition and influenza infection are more likely to require hospitalization than otherwise healthy children.[16,48]

Empirical antimicrobial therapy for the hospitalized child with pneumonia depends on the suspected pathogens and their presumed susceptibilities. For the vast majority of infants with pneumonia, viral pathogens are responsible and require only supportive therapy.[138] Rapid viral diagnostic tests can assist in the diagnosis, but some children with viral disease will have a bacterial coinfection that requires antimicrobial therapy. Perhaps best documented with influenza, infection may begin with rather benign upper respiratory tract symptoms that progress to a severity of illness that is unexpected or the infection may demonstrate a biphasic illness pattern with stable disease followed by subsequent deterioration, well documented during the 1918 influenza pandemic and in the 2009 H1N1 pandemic.[15]

Antiviral therapy exists for influenza virus. Most influenza A strains can be treated with neuraminidase inhibitors; in the past, adamantanes were effective treatment, but for the past several years, virtually all strains have been resistant. Most currently isolated strains of influenza B are susceptible to neuraminidase inhibitors. However, because substantial genetic variation occurs in influenza from year to year, resistance of influenza virus strains to any class of antiviral agents may develop and spread quickly. Globally, the World Health Organization tracks and reports resistance as strains are analyzed during the influenza season. In the United States, the CDC sequences a certain proportion of all strains isolated during the season to allow rapid detection of resistance to antiviral agents. Dosages of neuraminidase inhibitor agents that are currently recommended for influenza in children were evaluated in clinical trials that mandated treatment within 48 hours of onset of symptoms. Although earlier treatment will result in the most benefit in children,[75] children with serious illness that extends beyond 48 hours are still likely to benefit from therapy and should be treated.[8,56,97,114,144]

Oseltamivir is an orally available neuraminidase inhibitor in both tablet and suspension formulations. Zanamivir is available as inhalational therapy for older children who are capable of taking a deep breath on command. Dosing guidelines are available from both the American Academy of Pediatrics (AAP)[8] and the CDC.[40] Investigational neuroaminidase inhibitors that can be administered intravenously (peramivir, oseltamivir, and zanamivir), used for treatment of documented H1N1 infections during the H1N1 pandemic, are still available for compassionate investigational use, but are not yet approved by the U.S. Food and Drug Administration for general use.

For RSV pneumonia, controversy exists regarding the efficacy of inhaled ribavirin. Ribavirin has in vitro activity against RSV, but use of this drug for RSV infection is not routinely recommended in the management of lower respiratory tract disease because of marginal efficacy, cost, and potential toxicities to health care providers. New antivirals for RSV are under investigation.[160] Similarly, antivirals are under investigation for some less common, but potentially destructive viral pathogens causing pneumonia in immunocompromised hosts.

The etiology of bacterial pneumonia, as noted earlier, has been dramatically altered by effective PCVs for *H. influenzae* type b and *S. pneumoniae*. Disease caused by *H. influenzae* type b has been virtually eliminated in the developed world, and the susceptibility of *S. pneumoniae* to β-lactam agents such as penicillin G has improved dramatically. The increasing incidence of *S. aureus*, particularly methicillin-resistant strains, requires a more

TABLE 22-3 **Empirical Therapy of Suspected Community-Acquired Bacterial Pneumonia in Healthy Children**

Disease	Fully Immunized	Incompletely Immunized
Uncomplicated pneumonia (lobar or bronchopneumonia, without significant pleural effusion)	Ampicillin	Ceftriaxone or cefotaxime
Complicated pneumonia (with significant pleural fluid, empyema, abscess, pneumatocele)	Ampicillin plus Vancomycin*	Ceftriaxone plus Vancomycin*
Life-threatening, complicated pneumonia (with abscesses, pneumatoceles)	Ceftriaxone plus vancomycin plus nafcillin	

*Clindamycin may be substituted for vancomycin if local *Staphylococcus aureus* susceptibility data document rare resistance (<5%-10%).

aggressive approach to diagnosis of complicated pneumonia and consideration of the addition of empirical therapy active against all strains of *S. aureus*, in addition to that for *S. pneumoniae*. Empirical therapy is provided as the diagnostic evaluation for viral, bacterial, and atypical bacterial pathogens is in progress. Once a diagnosis is made, the most narrow-spectrum agent that is safe and well tolerated should be used.

Ampicillin or penicillin G intravenously is currently recommended for empirical therapy of acute bacterial CAP in fully immunized children (Table 22-3).[26] The use of antibiotics that are more active against penicillin-resistant pneumococci, such as ceftriaxone or vancomycin, is no longer routinely required with current low levels of β-lactam resistance. However, for children with incomplete immunization for pneumococcus, ceftriaxone or cefotaxime remain the preferred antimicrobials. The role of non–type b strains of *H. influenzae* in pneumonia in otherwise healthy children is difficult to define, because many reports of hospitalized children with pneumonia from whom non–type b strains of *H. influenzae* are recovered have underlying comorbidities, raising the possibility that these organisms may not represent a high risk to healthy, normal children. The use of ampicillin as empirical therapy will provide activity against the majority of non–type b strains as further work clarifies the role of this organism in pediatric CAP.

More difficult is the consideration of empirical therapy for CAP caused by *S. aureus*, particularly methicillin-resistant strains. Very little distinguishes between the clinical, laboratory, or radiographic characteristics of bacterial pneumonia caused by *S. aureus* in contrast to that caused by *S. pneumoniae*. Both can produce progressive disease associated with lung parenchymal destruction with empyema and signs and symptoms of systemic toxicity. Necrotizing pneumonia, particularly in the context of influenza coinfection, appears to be more characteristic of *S. aureus*, particularly with strains that are methicillin resistant.[39] Lung abscess formation with resulting complications may be more common with *S. aureus*.[39] With ampicillin as initial therapy of CAP, no antimicrobial activity is present against *S. aureus*, for either methicillin-susceptible or methicillin-resistant strains. Therefore, a high index of suspicion should be maintained for infection caused by *S. aureus* in children who do not respond to initial empirical therapy and children who present with complicated pneumonia, including pleural effusions, empyema, abscesses, and pneumatoceles. For these children with serious infection, the addition of vancomycin (or clindamycin if local susceptibility data document lack of resistance) to ampicillin while diagnostic studies are being pursued will provide adequate activity for either methicillin-susceptible or methicillin-resistant strains.[104] With β-lactam antibiotics thought to be preferred over vancomycin for susceptible strains of *S. aureus*, the addition of nafcillin to the regimen for optimal coverage of methicillin-susceptible strains is also recommended (see Table 22-3). For children who are diagnosed with MRSA pneumonia and do not respond clinically to vancomycin, linezolid is a reasonable alternative. In prospective studies in adults, linezolid therapy of nosocomial pneumonia caused by MRSA demonstrated outcomes that were at least as good as, if not better, than those with vancomycin.[168]

Definitive therapy, in contrast to *empirical* therapy, may be based on susceptibilities of the organisms to antimicrobials, using the narrowest spectrum, best tolerated, and most cost-effective agent. Recent recommendations have been made for specific antimicrobial agents, by pathogen, for both first-line and alternative agents, as well as agents for children who may be allergic to preferred agents.[26] For pneumococcus, intravenous penicillin G (or ampicillin) is preferred and for oral therapy, amoxicillin (or phenoxymethyl penicillin). For methicillin-resistant strains of *S. aureus*, intravenous vancomycin (or clindamycin) is preferred and for oral therapy, clindamycin (if susceptible) or linezolid. Insufficient prospective data are available to recommend trimethoprim-sulfamethoxazole therapy for MRSA pneumonia. For methicillin-susceptible strains, nafcillin or cefazolin should provide optimal therapy, with oral cephalexin for step-down therapy.

The duration of antimicrobial therapy in children in the developed world has primarily been studied in the context of antibiotic registration trials, comparing newer agents used for 10 days with those having previously been studied for a treatment course of 10 days. A notable exception is the azalide azithromycin, which displays unusual tissue-site pharmacokinetics, with drug exposure after 3 or 5 days of therapy comparable to 10 days of β-lactam therapy. Short-course (3 day) therapy with β-lactam amoxicillin or trimethoprim-sulfamethoxazole has been successful in the developing world for clinically defined pneumonia, but bacterial pathogen identification is infrequent in these studies, precluding conclusions about a pathogen-specific effective treatment course.[71]

Although the total course of therapy is usually 7 to 10 days for uncomplicated pneumonia, longer courses of 2 to 3 weeks may be required for more severe disease, particularly associated with pleural empyema or pulmonary abscesses. All therapy does not necessarily need to occur in a hospital setting if the child's clinical condition is improved, drainage procedures are no longer a concern, supplemental oxygen is no longer needed, and skilled nursing care is no longer required. Transition from intravenous inpatient therapy to daily intramuscular or intravenous outpatient therapy with prolonged half-life antibiotics, particularly β-lactams such as ceftriaxone or ertapenem, provides another option for the hospitalized child who still requires parenteral therapy based on issues of drug exposure within infected lung or pleural space or of issues of compliance.[151]

Depending on the response to therapy, oral step-down therapy often has been used to allow discharge from an inpatient setting. Although no prospective, controlled data are available to document the risks and benefits of this practice, clinical experience, often retrospectively documented, over several decades suggests that this practice is effective.[24] The duration of parenteral therapy before transition to oral therapy is based on the severity of the initial presentation and the rapidity of improvement. Improvement in fever, cough, tachypnea, and oxygen requirement, with improved activity and appetite, supported by a reduction in peripheral leukocyte counts or C-reactive protein or other acute-phase reactants are often used to help justify the transition to oral therapy.

Treatment for *M. pneumoniae* infection is less well studied in children than in adults.[12,96] Data extrapolated from adult studies suggest a modest benefit of therapy with tetracyclines and macrolides for illness of mild to moderate severity, with the assumption that children, particularly school-aged and adolescents, will respond similarly. Retrospective data from hospitalized children suggests that those who are treated have shorter inpatient admissions than those who do not receive therapy.[142] It is likely that children with moderate to severe disease will benefit from treatment with macrolides or tetracyclines (for children older than 7 years), prompting recommendations to test and treat for *Mycoplasma* spp. Azithromycin provides the shortest treatment course of the macrolides and is well tolerated, in contrast to erythromycin. Therapy with the respiratory fluoroquinolones has demonstrated treatment outcomes for adults not inferior to those with macrolides and tetracyclines, but fluoroquinolones are not considered agents of choice for children when other effective therapy exists. Of note, in a prospective, randomized study of preschool children with *Mycoplasma* lower respiratory tract infection documented serologically, amoxicillin-clavulanate demonstrated clinical outcomes equivalent to those of levofloxacin when evaluated by criteria for clinical cure at the end of therapy.[25] These results suggest the possibility of a high rate of spontaneous clinical resolution in this younger age group or that improvement may have occurred at an earlier time in the treatment course, not documented by the study design used.

Chlamydia trachomatis has been identified as an uncommon cause of afebrile pneumonia in very young infants, 2 to 12 weeks of age, after birth to a mother with genital infection. *C. pneumoniae* has been documented to cause atypical pneumonia in school-aged children and adolescents.[34,73] However, the clinical impact of antimicrobial therapy of *C. pneumoniae* lower respiratory tract infection in older children has been difficult to define, probably because of the difficulties in making an accurate diagnosis of active infection, as well as the relatively benign and self-resolving nature of infection.[21]

PREVENTION

Over the last two decades, great strides have been made in the prevention of CAP. The development of PCVs against both *H. influenzae* type b and *S. pneumoniae* has resulted in significant declines in cases of bacterial pneumonia in countries that have introduced these vaccines.[101,120,132] Both vaccines are provided as part of the routine childhood immunization series for all children in resource-rich areas of the world and should also be made available for all children in the developing world. Children can be protected against CAP caused by viral pathogens. Influenza vaccine is recommended for all children 6 months and older and prevents CAP resulting from influenza.[8] In addition, increasing evidence shows that bacterial CAP may occur concomitantly with influenza or as a secondary infection after influenza.* The risk for hospitalization with CAP resulting from RSV, the most common pathogen identified in infants, can be modified by the administration of palivizumab to infants with high-risk conditions.[58,148] Given the expense of this intervention, guidelines for use in high-risk infants should be followed to maximize cost-effectiveness.[5,116] Finally, the PIDS/IDSA CAP Guidelines, the CDC, and the AAP support the immunization of parents and other caregivers against influenza, to protect children who are too young to be immunized[29,99]; the AAP also recommends immunizing parents against other vaccine-preventable infections, including CAP.[29,99]

CHAPTER 23

Children's Interstitial Lung Disease and Hypersensitivity Pneumonitis

Minh L. Doan • Leland L. Fan

Children's interstitial lung disease (ILD) encompasses a heterogeneous group of uncommon, diffuse lung disorders with varying clinical presentations and morbidity.[45] In many of these disorders, injury to the alveolar wall gives rise to an inflammatory response with subsequent repair that potentially can lead to pulmonary fibrosis. Infections of the lung, either chronic or acute with postinfectious sequelae, form the largest category of children's ILD in the immunocompetent and immunocompromised host. The discussion in this chapter is focused on the entities that are caused by or associated with infection and the entities that mimic community-acquired pneumonia.

CLASSIFICATION

An updated classification of the conditions that encompass children's ILD is presented in Table 23-1. Although a complete description of each disorder is beyond the scope of this chapter, certain conditions warrant brief mention because major differences exist between adult ILD and children's ILD in terms of types and distribution of disease. Usual interstitial pneumonitis, a progressive and fatal disorder, is the most common form of adult idiopathic ILD, but it probably does not occur in children. Also, hypersensitivity pneumonitis (HP) in adults is caused by a variety of occupational exposures but in children usually is caused by exposures to an avian antigen. In addition, several entities, such as neuroendocrine cell hyperplasia of infancy and pulmonary interstitial glycogenosis, are unique to infants and young children. Finally, the genetic basis for certain types of familial lung diseases has been linked to mutations in genes involved in surfactant metabolism.[69,121,122,160] With the exception of surfactant protein C and thyroid transcription factor–1 *(TTF-1)* mutations, because of high mortality rates, these disorders have been found mostly in children.

Disorders Associated with Infection

The role of infectious agents, such as adenovirus,[187] influenza,[99] *Mycoplasma*,[168] and *Chlamydia*,[6] in the development of chronic lung disease in children has been well documented. Virtually any organism that infects the lower respiratory tract is capable of producing chronic, diffuse lung disease if the injury is severe enough, although most infected children have acute, self-limited disease that resolves completely.

Bronchiolitis Obliterans

Probably the best example of postinfectious chronic lung disease is found in children who develop bronchiolitis obliterans after having severe adenoviral pneumonia.[187] Bronchiolitis obliterans is characterized by a fibrosing process of the small airways that results in severe, irreversible obstruction of the airways. Clinically, patients present with tachypnea, crackles, wheezing, and a productive cough that persist for more than 8 weeks after the initial illness. Chest radiographs commonly show a mixed pattern of hyperinflation, persistent atelectasis, and peribronchial thickening; on high-resolution computed tomography (HRCT) in which both inspiratory and expiratory images are obtained, a combination of mosaic perfusion due to air trapping, central bronchiectasis, and vascular attenuation is highly specific for bronchiolitis obliterans, although not entirely sensitive.[25,118] Occasionally, severe involvement of one lung leads to the development of a unilateral, small, hyperlucent lung, known as Swyer-James syndrome.[187] Pulmonary function testing demonstrates an obstructive pattern characterized by a disproportionate reduction in the midexpiratory flow (FEF_{25-75}) that is usually fixed, although a small response to bronchodilator may be seen.[118]

Patients with severe adenovirus pneumonia have been shown to have immune complexes containing adenovirus antigen in the lung and increased serum levels of interleukin-6, interleukin-8, and tumor necrosis factor–α.[116,117] These studies suggest that abnormal or excessive host immunologic and inflammatory responses may be important in the development of chronic lung disease from adenovirus in infants and young children. Although lower respiratory tract infection with *Mycoplasma*,[27] respiratory syncytial virus, parainfluenza, influenza, measles, varicella,[189] and pertussis[29] also can result in bronchiolitis obliterans, adenovirus is the most common etiologic agent. The need for mechanical ventilation during the initial illness is a strong independent

TABLE 23-1 Classification of Children's Interstitial Lung Diseases

Disorders Unique to Infancy

Diffuse developmental disorders
- Acinar dysplasia
- Congenital alveolar dysplasia
- Alveolar capillary dysplasia with misalignment of pulmonary veins

Growth abnormalities
- Chronic neonatal lung disease (in premature and term infants)
- Secondary pulmonary hypoplasia
- Chromosomal abnormalities (i.e., trisomy 21)
- Associated with congenital heart disease

Surfactant dysfunction disorders
- Surfactant protein B mutations
- Surfactant protein C mutations
- *ABCA3* mutations
- *TTF-1* mutations
- Histology consistent with surfactant dysfunction disorder without recognized genetic disorder

Neuroendocrine cell hyperplasia of infancy

Pulmonary interstitial glycogenosis

Primary Lung Disease

Idiopathic interstitial pneumonias
- Nonspecific interstitial pneumonia
- Cryptogenic organizing pneumonia
- Acute interstitial pneumonia
- Desquamative interstitial pneumonia
- Lymphocytic interstitial pneumonia

Alveolar hemorrhage syndromes
- Includes syndromes with and without pulmonary capillaritis

Pulmonary alveolar proteinosis
- Includes congenital, primary, and secondary causes

Pulmonary microlithiasis

Pulmonary vascular disorders

Pulmonary lymphatic disorders
- Lymphangiomatosis
- Lymphangiectasis

Pulmonary infiltrates with eosinophilia
- Includes primary and secondary causes (drugs, parasites, infections, toxins)

Systemic Disorders with Pulmonary Involvement

Connective tissue disease
- Includes systemic lupus erythematosus, systemic sclerosis, Sjögren syndrome

Malignancies

Histiocytosis

Sarcoidosis

ILD of Specific (Known) Cause

Storage disorders

Aspiration syndromes

Postinfectious bronchiolitis obliterans

Drug-induced lung disease

Hypersensitivity pneumonitis

risk factor for the subsequent development of this disease.[35]

Lymphocytic Interstitial Pneumonitis

Well recognized because it is an acquired immunodeficiency syndrome (AIDS)–defining condition in children infected with human immunodeficiency virus (HIV),[22] lymphocytic interstitial pneumonitis (LIP) also occurs in association with other immunodeficiencies, such as common variable immunodeficiency,[178] autoimmune disorders such as juvenile rheumatoid arthritis, and Sjögren syndrome,[44,104,177] and in idiopathic and familial forms.[123] LIP is not a true interstitial pneumonitis but rather is a form of pulmonary lymphoproliferative disease. It is characterized histologically by a diffuse infiltrate of mature lymphocytes, along with smaller numbers of plasma cells and histiocytes, into the pulmonary interstitium, alveolar wall, and along lymphatic pathways.[93,94] Generally, the lymphocytes are polyclonal, with B cells and a variety of T cells being identified.[135] The etiology of LIP remains unknown, but it is thought that coinfection with Epstein-Barr virus (EBV) and HIV may produce the lymphoproliferative response.[5,57,89] EBV has also been implicated in LIP in non–HIV-infected patients.[107]

LIP occurs in 30 percent of children infected perinatally with HIV and typically presents between the second and third years of life as an insidious onset of cough, tachypnea, dyspnea, and hypoxemia.* Bilateral nontender parotid enlargement is frequently present and may help to differentiate LIP from other pulmonary complications of HIV infection.[158,161] Chest radiographs characteristically reveal a diffuse, symmetric reticulonodular or nodular pattern, occasionally with mediastinal or hilar adenopathy,[108] although HRCT is more sensitive and allows for the identification of the subpleural and perilymphatic distribution of the micronodules.[10] Among HIV-infected children, the incidence of acute lower respiratory tract infection is higher in children with LIP,[158] and these patients ultimately may develop bronchiectasis.[159]

Other Conditions

Other pediatric chronic lung diseases have been associated with various infectious agents. The role of perinatal infection or colonization with *Ureaplasma urealyticum* in inducing pulmonary inflammation and the subsequent development of bronchopulmonary dysplasia in premature neonates remains controversial.[11,86,154] Parvovirus has been linked to autoimmune disease associated with ILD and other organ involvement.[13] Finally, attempts have been made to link *Stachybotrys chartarum* and its mycotoxins to acute and recurrent pulmonary hemorrhage in infants, although a causal relationship has not been proven.[23]

In a prospective study of immunocompetent children with chronic diffuse infiltrates, Fan and coworkers[60] found an infectious agent as the underlying cause in 10 (20%) of 51 children with ILD. Identified agents included adenovirus alone in 4 children, adenovirus and cytomegalovirus in 2, varicella in 1, EBV in 1, *Chlamydia* in 1, and *Toxocara* in one. Chronic infections or long-term sequelae from acute infections account for many cases of ILD of known etiology in children.

Entities That May Mimic Community-Acquired Pneumonia

Acute Eosinophilic Pneumonia

Acute eosinophilic pneumonia is the most severe form of the idiopathic eosinophilic pneumonias. It is characterized histologically by very large numbers of eosinophils infiltrating the alveoli and interstitium, with resultant acute respiratory failure. Acute eosinophilic pneumonia can be idiopathic or result from inciting triggers such as drugs (minocycline, sertraline) and inhalational exposures (recent-onset cigarette smoking). Patients present with acute onset of fever, dyspnea, and cough; pleuritic chest pain; and myalgias. On examination, crackles are present in 80 percent of patients; wheezing is a rare manifestation. Hypoxemia is uniformly present, and patients can progress rapidly to respiratory failure with a clinical picture of acute respiratory distress syndrome. In contrast to patients with other eosinophilic lung diseases, patients with acute eosinophilic pneumonia generally do not have significant peripheral eosinophilia (>350 cells/mm^3) on presentation as a diagnostic clue. Chest radiographs and CT scans show bilateral infiltrates with a variable mix of interstitial and alveolar patterns; pleural effusions are present in 50 percent of cases. Flexible bronchoscopy to obtain a true bronchoalveolar lavage (BAL) is necessary for the diagnosis, and fluid analysis shows marked eosinophilia (>20%) in most patients. Although pleural fluid also has increased eosinophils, this finding in isolation is not specific for acute eosinophilic pneumonia. Treatment with corticosteroids (i.e., methylprednisolone 2 to 4 mg/kg/day) usually results in a rapid and complete resolution, and recurrences have not been reported.[3,143]

Pulmonary Vasculitis

In children, the spectrum of pulmonary vasculitides includes granulomatosis with polyangiitis (Wegener), Churg-Strauss syndrome, microscopic polyangiitis, and pulmonary capillaritis. These disorders can present as diffuse alveolar hemorrhage, with fever, dyspnea, hemoptysis (may not present in a third of patients), anemia, and patchy alveolar infiltrates on chest radiographs. Other patients may have fever and cavitary or nodular lesions on imaging.[80] Diffuse alveolar hemorrhage can be diagnosed with BAL, when sequentially recovered aliquots of fluid show persistently bloody return. If hemosiderin-laden macrophages are seen on BAL cytology, then this suggests that the blood has been present in the alveolar spaces for at least 3 days and is not the result of the bronchoscopy itself.[54] Renal involvement may sometimes be present, with microscopic hematuria and red blood cell casts seen on urinalysis. A positive serum antineutrophil cytoplasmic antibody (ANCA) may be seen, with antiproteinase-3 antibody resulting in a cytoplasmic (c-ANCA) staining pattern being associated with Wegener granulomatosis and with antimyeloperoxidase antibody giving a perinuclear (p-ANCA) pattern seen in Churg-Strauss syndrome and microscopic polyangiitis.[37] The presence of significant peripheral and pulmonary eosinophilia would support the diagnosis of Churg-Strauss syndrome.[15] Pulmonary capillaritis is associated with a variety of conditions and requires a surgical lung biopsy for diagnosis because it may present as an ANCA-negative, hematuria-negative diffuse alveolar hemorrhage syndrome.[68] Therapeutic options for pulmonary vasculitis include systemic corticosteroids, cyclophosphamide, intravenous immunoglobulin, and rituximab[21]; aggressive treatment is required in severe cases.

Connective Tissue Disorders

Pulmonary manifestations can precede other systemic findings in children with systemic lupus erythematosus,[34] juvenile rheumatoid arthritis,[144] and Behçet disease,[178] and these patients may present with acute respiratory symptoms associated with fever. In acute lupus pneumonitis, signs and symptoms include high fevers, dyspnea, tachypnea, crackles, and cyanosis. Chest radiographs may show areas of consolidation and pleural effusions or a pattern of interstitial infiltrates with elevation of the hemidiaphragms.[110] Other pulmonary manifestations of systemic lupus erythematosus include pulmonary hemorrhage, pulmonary hypertension, ILD, pneumothorax, and shrinking lung syndrome. Multisystem involvement, including renal and skin, may provide clues to the underlying diagnosis. Treatment usually requires corticosteroids and other immunosuppressive agents.[34]

Hypersensitivity Pneumonitis

Acute episodes of HP may present as fever, cough, dyspnea, and pulmonary infiltrates (see later section for a more detailed discussion).

CLINICAL PRESENTATION

Most children with ILD have insidious symptoms that may go unrecognized for years. Some children have been misdiagnosed as having asthma and have been treated with bronchodilators and inhaled corticosteroids.[64] Although a history of wheezing can be elicited in half of patients, it can be documented by physical examination in only approximately 20 percent of cases. Clinical suspicion for children's ILD should arise when patients meet at least three of the four following criteria: (1) presenting symptoms of dyspnea, tachypnea, retractions, cough, exercise intolerance, or respiratory failure; (2) presenting signs of crackles, failure to thrive, clubbing, or respiratory failure; (3) hypoxemia; and (4) diffuse abnormality on chest radiographs or CT not attributable to other known processes.[60]

A careful history should be taken to assess the severity of the disease and to obtain information that may contribute to establishing a diagnosis. A search for precipitating factors should include a history of feeding difficulties that may suggest aspiration; any prior acute or severe respiratory tract infections; and environmental exposures, especially to birds or molds. Hemoptysis may indicate a pulmonary vascular disorder or hemosiderosis. Joint disease or rash may indicate a systemic process, such

as a connective tissue disease. A family history of relatives or siblings with similar respiratory conditions may be clues to genetic or familial lung diseases, such as inborn errors of surfactant metabolism.

On physical examination, tachypnea and retractions often are observed, and crackles commonly are heard, particularly at the bases. In severe cases, cyanosis, clubbing, an accentuated pulmonic component of the second heart sound, and evidence of growth failure are seen. Oxygen saturation usually is normal under all conditions in most patients with mild disease, but desaturation may occur with exercise or during sleep as the disease progresses and ventilation-perfusion mismatch ensues. Patients with more advanced disease are hypoxemic at rest.

DIAGNOSTIC EVALUATION

A systematic approach to children's ILD is essential to physicians confronted with such a large differential of rare conditions. Diagnostic studies can be divided into studies used to assess the extent and severity of disease, to identify disorders that predispose to ILD, and to identify the primary ILD (Table 23-2). In adults with ILD, Raghu[137] suggested a diagnostic process that employs a thorough history and physical examination first, noninvasive tests next, and then invasive studies, including BAL and transbronchial biopsy followed by open lung biopsy if the previous less invasive studies do not provide a specific diagnosis. Based on experience from a retrospective chart review of 48 children with ILD, Fan and colleagues[64] independently developed an algorithm remarkably similar to that of Raghu's and used it prospectively in the evaluation of 51 children presenting with ILD.[60] In that study, a specific diagnosis was established by history and physical examination alone in 1 patient; noninvasive studies alone in 8 others; and invasive studies, including lung biopsy, in another 26. Of the remaining patients, 8 had a suggestive diagnosis and 8 had no specific diagnosis. This study suggests that a systematic approach to the diagnosis of children's ILD is useful and that some patients can be diagnosed with noninvasive studies, but most patients require invasive studies, including lung biopsy.

TABLE 23-2 **Diagnostic Studies for Pediatric Interstitial Lung Disease**

To Assess Extent and Severity of Disease
Chest radiography, high-resolution computed tomography
Pulmonary function studies: spirometry, pulse oximetry and arterial blood gases (resting, sleeping, and with exercise), diffusion, pressure-volume curve, infant studies
Electrocardiography, echocardiography
To Identify Primary Disorders That Predispose to Interstitial Lung Disease
HIV test
Immune studies: immunoglobulins including IgE, skin tests for delayed hypersensitivity, response to immunizations, T- and B-cell subsets, complement, others as indicated
Barium swallow, pH/impedance probe
DNA analyses for mutations in the surfactant protein B, surfactant protein C, and *ABCA3* and *TTF-1* genes
To Identify Primary Interstitial Lung Disease
Antinuclear antibody
Angiotensin-converting enzyme
Antineutrophil cytoplasmic antibody
Antiglomerular basement membrane antibody
Hypersensitivity screen
Infectious disease evaluation—cultures, titers, skin tests
Cardiac catheterization (in selected cases)
Bronchoalveolar lavage and transbronchial biopsy
Transthoracic biopsy

HIV, human immunodeficiency virus.

Pulmonary Function Tests

In children who are old enough to undergo pulmonary function tests, standard spirometry typically shows a pattern of restrictive lung disease, with reduced forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1), and a normal or elevated FEV_1/FVC ratio.[64] On measurement of lung volumes, although the total lung capacity (TLC) often is low, the residual volume (RV) may be normal or elevated, resulting in an increased RV/TLC ratio that suggests air trapping and a mixed restrictive/obstructive pattern. These findings also can be documented in infants and young children with the use of infant pulmonary function testing techniques.

High-Resolution Computed Tomography

In the evaluation of children's ILD, HRCT is an important diagnostic modality used to provide precise detail about the extent and distribution of the lung disease, to select favorable sites for surgical lung biopsy, and, when classic patterns of abnormalities are seen, to either make a confident diagnosis for some conditions or to guide specific but less-invasive testing (genetic testing, autoantibody levels, bronchoscopy) for other conditions.[181] However, although a chest CT can be readily ordered, it is often not performed in the manner necessary to optimally evaluate for diffuse lung diseases in children. It is therefore critical that adequate consideration be given for the technique requested, so as to avoid an unhelpful exposure to ionizing radiation to the patient.

With HRCT, the thin (usually 1.25 mm or 0.625 mm in thickness) sections or reformatted scans obtained avoid the volume averaging that occurs with 2.5- to 5-mm sections, which obscures the fine parenchymal detail and airway abnormalities. The conventional noncontiguous axial HRCT technique results in lower radiation exposure but is more technically demanding, has more motion artifact, risks missing abnormal findings, and does not allow for a complete evaluation of the central airways and mediastinum. On the other hand, the multidetector CT scanners now widely available can rapidly acquire a

volumetric data set of the entire thorax, from which thin reformatted images can be shown in a contiguous fashion or at a specified interval, depending on the number of images desired for review. On some scanners, the bone reconstruction algorithm gives better lung image resolution than does the lung reconstruction algorithm. If appropriate pediatric protocols are used, a volumetric pediatric chest CT scan with high-resolution reformatted images can be performed with radiation doses of less than 1.5 mSv (equivalent to 6 months of natural background radiation exposure).[74]

Obtaining high-quality CT images of the lungs requires the avoidance of respiratory motion artifact. In younger children and infants in whom cooperation for breath-holding is impossible and in whom rapid respiratory rates especially predispose to motion artifact, a sedated controlled-ventilation CT technique can be used.[103] Giving several assisted deep breaths using mask ventilation to these sedated young children results in a short period of apnea during which the lungs can be fully inflated to obtain the routine inspiratory images. Expiratory images should also be considered to assess for air trapping and can be acquired after allowing for passive deflation of the lungs or with voluntary end-expiratory breath-holding. General anesthesia produces similar results, although frequent large sigh breaths are necessary to prevent dependent atelectasis, which occurs within minutes of intubation.[74]

In studies that have investigated the diagnostic accuracy of HRCT in pediatric diffuse lung disease, the first-choice diagnosis was proven correct in 38 to 61 percent of cases by subsequent surgical lung biopsy.[36,105,183] CT of pediatric diffuse lung diseases detailing the classic findings seen with certain of these conditions has been recently reviewed.[74]

Bronchoalveolar Lavage

BAL via flexible bronchoscopy allows for sampling of the alveolar lining fluid to assess its gross appearance and to send for measurement of cell count and differential, cytologic examination, microbial cultures, as well as molecular and biochemical analyses, all of which may be helpful in the evaluation of certain cases of children's ILD. A milky appearance of the BAL fluid with a layering of sediment strongly suggests pulmonary alveolar proteinosis, whereas the progressively bloody appearance of the fluid in sequential aliquots indicates the presence of an alveolar hemorrhage syndrome. Normal indices for pediatric BAL fluid have been described, against which abnormal results can be compared.[56] Finding significant eosinophilia or lymphocytosis in the BAL would substantially narrow the differential diagnoses, and detection of lipid-laden or hemosiderin-laden macrophages can serve as sensitive, albeit not specific, markers for aspiration or alveolar hemorrhage syndromes. Cytologic examination can also be used to diagnose pulmonary alveolar proteinosis, lysosomal storage disorders, and histiocytosis.[63]

The most common indication for pediatric BAL has been to detect infection in the immunocompromised host. The use of quantitative bacterial cultures may help to differentiate whether recovered organisms represent true infection, colonization, or contamination, whereas polymerase chain reaction (PCR) techniques allow for increased sensitivity in detecting *Pneumocystis jiroveci* pneumonia in non–HIV-immunocompromised patients[128] and for the rapid detection of *Mycobacterium tuberculosis*.[131] Cytologic examination may identify cases of aspergillosis not otherwise detected by culture alone,[4] and measurement of galactomannan levels in BAL has also been used for early diagnosis of invasive aspergillosis.[46]

When BAL should be performed may be important, because investigators have shown in a murine model that hemosiderin-laden macrophages first appear at 3 days, peak at 1 week, and persist in small numbers for 2 months after a single episode of hemorrhage.[54] In adult hematopoietic stem cell transplantation recipients with new pulmonary infiltrates, the diagnostic yield of BAL was highest when performed within 24 hours of presentation.[157]

Finally, while bronchial washings obtained via a suction catheter introduced through an endotracheal tube have proven useful in the evaluation of ventilator-associated pneumonia,[149] they do not adequately sample the alveolar lining fluid and therefore give a different cellular profile than that obtained by bronchoscopic BAL.[92] This discrepancy may result in missed detection of conditions such as acute eosinophilic pneumonia if only the former is performed.

Lung Biopsy

As in adult ILD, lung biopsy is the gold standard for establishing the diagnosis of children's ILD because most diseases are classified in terms of previously defined histopathologic patterns. Although transbronchial or percutaneous needle biopsy may be helpful in certain conditions, a transthoracic approach, usually by video-assisted thoracoscopic surgery (VATS), remains the gold standard for obtaining tissue adequate for diagnosis. Technical advances and now widespread experience with VATS, including in infants,[146] make it the method of choice, especially in light of research demonstrating comparable diagnostic yield in the evaluation of children with ILD (54% with VATS, 57% with open-lung biopsy).[61] Selection of biopsy sites should be determined by findings on HRCT, which may, in selected circumstances, actually obviate the need for lung biopsy to establish the diagnosis.

Lung biopsy material must be processed in a consistent manner to ensure optimal interpretation, and a protocol for such handling was published based on the recommendations of the Children's Interstitial Lung Disease (chILD) Pathology Group.[98] A general scheme for division of the biopsy specimen is as follows: (1) microbiology cultures, 35 percent; (2) snap-frozen for PCR or other molecular studies, 10 percent; (3) snap-frozen in cryomatrix for immunofluorescent, laser capture, or other studies requiring frozen sections, 10 percent; (4) fixed in glutaraldehyde for electron microscopy, less than 5 percent; (5) imprints for cytologic examination or rapid identification of organisms, 0 percent; and (6) expanded and fixed in formalin (methods previously described[48]) for light microscopy, 40 percent. It is

crucial that the biopsy material be interpreted by a pathologist with considerable expertise in pediatric lung disease because the normal lung of an infant differs greatly from that of an older child or adolescent and any pathologic finding needs to be interpreted in light of the normal age-dependent variations of lung architecture.

TREATMENT

Supportive care is important in the management of children's ILD. Good nutrition is paramount, to the extent that gastrostomy feedings should be considered in selected patients who have poor weight gain despite maximal conventional treatment.[181] Nocturnal or continuous oxygen therapy should be provided in children who are hypoxemic to decrease the risk for the development of pulmonary hypertension. Annual influenza vaccination through the injectable route should be given. Avoiding inhalant hazards such as tobacco smoke should be stressed. Patients with underlying systemic disorders need primary treatment for that disorder, such as intravenous gamma globulin for hypogammaglobulinemia. Specific therapy for primary ILD should be used when possible, such as aggressive management of identified causes of aspiration syndromes, lung lavage and inhalational granulocyte-macrophage colony-stimulating factor for certain types of pulmonary alveolar proteinosis,[142,191] and interferon-α for pulmonary hemangiomatosis.[130] When environmental agents such as bird antigens are causative, avoiding contact with them is crucial (see later section on HP).

Generally, corticosteroids remain the treatment of choice for most patients with ILD on the presumption that suppression of inflammation may reduce the risk for developing fibrosis.[62] Although controlled clinical studies are lacking,[101] corticosteroids have been used to treat such diverse types of diffuse lung diseases as desquamative interstitial pneumonitis, nonspecific interstitial pneumonitis, acute interstitial pneumonia, cryptogenic organizing pneumonia, lymphocytic interstitial pneumonia, HP, eosinophilic pneumonia, diffuse alveolar hemorrhage, ILD associated with connective tissue diseases, and surfactant protein C mutations.[173,180] In a retrospective study of pediatric ILD by Fan and coworkers,[64] corticosteroids were judged to be effective in 40 percent (12 of 30) of treated children in terms of improved clinical status, decreased oxygen requirements, and improved pulmonary function. A trial of prednisone or equivalent corticosteroid in a dose of 1 to 2 mg/kg/day for at least 6 to 8 weeks probably is warranted, although it may be preferable to instead use intravenous pulses of methylprednisolone 30 mg/kg, with a maximum dose of 1 g, given for either 3 consecutive days every month or 1 day every week, based on experience that pulse intravenous therapy is at least as effective as oral therapy and has fewer side effects.[181]

Alternative immunomodulatory agents that have also been used include hydroxychloroquine, azathioprine, cyclophosphamide, methotrexate, cyclosporine, intravenous gamma globulin, and mycophenylate mofetil.[150] Of these, hydroxychloroquine probably has been used most frequently.[7,64,158,164] The precise mechanism of action is unknown, but chloroquine and hydroxychloroquine have shown immunosuppressive effects with the ability to inhibit the functional capabilities of monocytes and the generation of antibody-forming cells. Hydroxychloroquine is preferred over chloroquine because the former has less retinal toxicity. The recommended dose in children for the treatment of ILD is 10 mg/kg/day. Additionally, there has been a case report describing the successful use of infliximab, an anti–tumor necrosis factor–α monoclonal antibody, in reversing bronchiolitis obliterans in a hematopoietic stem cell transplant recipient.[67] Finally, treatment regimens for ILD associated with systemic sclerosis,[184] Langerhan cell histiocytosis,[115] and Wegener granulomatosis[18] have been reviewed. The fact that many alternative pharmacologic approaches are considered for children and adults with ILD implies that conventional therapy often is ineffective. New strategies are being developed based on animal models of pulmonary fibrosis and more recent advances in the cellular and molecular biology of inflammatory reactions. Such therapies would be directed against the action of certain cytokines, oxidants, and growth factors that may be involved in the fibrotic process. One such potential agent is pirfenidone, which may have some clinical benefit in the treatment of idiopathic pulmonary fibrosis in adults.[170] The potential to deliver specific inflammatory inhibitors or inhibitors of collagen biosynthesis directly to the lung via aerosolization suggests that disease processes in the lung may be more amenable to novel therapies than are disease processes in other internal organs.

Lung transplantation can be used as a final therapeutic modality for some forms of children's ILD that progress to irreversible respiratory failure secondary to pulmonary fibrosis. Although the overall 5-year survival after lung transplantation is still disappointing at approximately 50 percent,[12] it appears that outcomes for children with diffuse lung disease are comparable to those undergoing transplantation for cystic fibrosis or pulmonary hypertension.[138] In certain systemic conditions, such as hereditary pulmonary alveolar proteinosis, however, transplantation may not be appropriate because the primary disease may recur in the transplanted lungs.[109,153]

OUTCOME

The prognosis of children with ILD varies. Infants with neuroendocrine cell hyperplasia of infancy generally do well, although they may be symptomatic and require oxygen for years.[49] At the other end of the spectrum, children with growth failure, pulmonary hypertension, and severe fibrosis do poorly. A survey that likely included many different types of pediatric interstitial lung diseases found an overall mortality rate of 15 percent.[47]

Fan and Kozinetz[59] reviewed the outcome of 99 children with chronic ILD seen in Denver, Colorado, over 15 years (1980-1994). As expected, a wide variety of disorders were encountered, and 15 recorded deaths occurred, with a probability that a patient would survive to 24 months, 48 months, and 60 months after onset of symptoms of 83 percent, 72 percent, and 64 percent,

respectively. Of the clinical features present at the time of initial evaluation, weight less than the fifth percentile, crackles, clubbing, family history of ILD, and symptom duration were not associated with decreased survival rates. A severity of illness score, based on increasing levels of hypoxemia and the presence or absence of pulmonary hypertension, was related significantly to survival, with an increasing score associated with a higher probability of decreased survival rates. A simple scoring system seems to be a useful measure of outcome in children with ILD.

HYPERSENSITIVITY PNEUMONITIS

HP, also known as *extrinsic allergic alveolitis*, is a form of immune-mediated ILD that develops in response to repeated inhalation of finely dispersed organic antigens.[40] HP should be considered in the differential diagnosis of a child who presents with acute or chronic respiratory symptoms associated with fever,[16] and obtaining an environmental exposure history is essential to arrive at the proper diagnosis. A wide variety of organic particles, including mammalian and avian proteins, fungi, thermophilic bacteria, and certain low-molecular-weight volatile and nonvolatile chemical compounds, are known to induce HP in susceptible individuals.[2] Certain systemic medications, such as ciprofloxacin,[165] dapsone,[174] and methotrexate,[41] also have been reported as triggers.

In general, three forms of HP have been described: (1) acute (or episodic), with improvement between attacks; (2) insidious (gradual onset and progressive course) with superimposed acute episodes; and (3) insidious without acute attacks.[79] Although exposure to antigens capable of provoking HP occurs commonly in the home and work environment, the overall incidence of the condition in the general population is low.[16,163] It is estimated that only 5 to 15 percent of individuals exposed to high levels of a specific organic antigen develop clinical disease.[65,184]

Pathology and Pathogenesis

Pathologically, HP is characterized by a diffuse, lymphoplasmacytic cell infiltration of the small airways and pulmonary parenchyma, often with associated multinucleated giant cells containing cholesterol clefts and poorly formed, non-necrotizing granulomas.[70] Foamy macrophages are seen commonly in the airspaces. With advanced disease, interstitial and intra-alveolar fibrosis develops that is indistinguishable from other causes of pulmonary fibrosis.

The mechanisms by which organic dusts induce these characteristic pathologic features of the disease are not completely understood, but it is thought that both type III (immune complex–mediated) and type IV (delayed) hypersensitivity mechanisms are involved.[133] A type III reaction is suggested by the presence of precipitating antibody to the offending antigen, immune complex deposition, and activation of complement. A type IV reaction is suggested by an increased percentage of T lymphocytes in BAL fluid, with a strong predominance of $CD8^+$ subsets and a low CD4/CD8 ratio, and the presence of granulomas on lung biopsy specimen. Considering the small proportion of exposed individuals who develop clinical symptoms, complex interactions among the nature of the antigen, the intensity and duration of the exposure, and the host response in affected individuals most likely are involved. Additionally, genetic factors[19] and possibly associated viral infections[43] appear to contribute to susceptibility, whereas cigarette smoking (nicotine) seems to confer a protective effect.[84] Familial cases of HP have been identified.[50]

Etiology

As shown in Table 23-3, HP in adults is caused by a wide variety of occupational and environmental exposures.[155] In contrast, in children, HP is caused mainly by exposure to an array of domestic birds (69%) and fungi (29%), based on a review of 164 reported pediatric cases. In HP due to bird exposure (bird fancier's lung), bird droppings and feathers are the major sources of the offending antigens.[112] Although exposure to pet birds is usually the cause,[119] even low levels of environmental exposure to wild birds in the yard or birds raised by a neighbor may be enough to induce clinical HP,[97,152] as may contact with feather-filled household items such as feather pillows, down comforters, and feather duvets.[16,83,119] The onset of clinical disease typically follows months to years of continuous or intermittent exposure to the offending antigen,[79] and it has been demonstrated that bird antigens can persist for months in the home environment even after removal of the birds.[39] Possible sources of mold exposure are varied and can include contaminated air humidifiers,[134] indoor hydroponics,[53] organic compost in a play area,[1] moist hay,[172] and even wind instruments,[113] in addition to overt mold contamination in areas of water damage or in poorly ventilated spaces exposed to moisture.[81,171]

Clinical Presentation

Although a wide variety of antigens can induce HP, the immunologic response and clinical presentation are similar. In the reported pediatric cases referenced previously, the mean age (± standard deviation) was 9.7 (± 4.0) years. The youngest reported patient with HP developed symptoms at 10 weeks of age.[172]

Acute episodes of HP mimic flulike illnesses, manifesting as high fevers, chills, dry cough, dyspnea, myalgias, and malaise. These symptoms begin several hours after exposure and diminish during the next 12 to 24 hours, provided that no additional exposure to the antigen occurs. Physical examination reveals a dyspneic, ill-appearing child, often with bibasilar crackles. Transient hypoxemia and nodular pulmonary infiltrates often are present. Hospitalization for presumed pneumonia often leads to resolution of symptoms due to removal from the causative environment.

More commonly, children present with more insidious and progressive symptoms, which may or may not be punctuated by intermittent acute manifestations. In the reported pediatric cases in which the following specific symptoms were recorded, exercise intolerance was

TABLE 23-3 **Etiologic Agents of Hypersensitivity Pneumonitis**

Disease	Antigen	Source
Fungal and Bacterial		
Farmer's lung	*Faeni rectivirgula*	Moldy hay, grain, silage
Ventilation pneumonitis; humidifier lung; air conditioner lung	*Thermoactinomyces vulgaris, Thermoactinomyces sacchari, Thermoactinomyces candidus, Klebsiella oxytoca*	Contaminated forced air systems, water reservoirs
Bagassosis	*T. vulgaris*	Moldy sugarcane (i.e., bagasse)
Mushroom worker's lung	*T. sacchari*	Moldy mushroom compost
Suberosis	*Thermoactinomyces viridis, Penicillium glabrum*	Moldy cork
Detergent lung; washing powder lung	*Bacillus subtilis* enzymes	Detergents (during processing or use)
Malt worker's lung	*Aspergillus fumigatus, Aspergillus clavatus*	Moldy barley
Sequoiosis	*Graphium, Pullularia,* and *Trichoderma* spp.; *Aureobasidium pullulans*	Moldy wood dust
Maple bark stripper's lung	*Cryptostroma corticale*	Moldy maple bark
Cheese washer's lung	*Penicillium casei, A. clavatus*	Moldy cheese
Woodworker's lung	*Alternaria* spp., wood dust	Oak, cedar, and mahogany dust; pine and spruce pulp
Paprika slicer's lung	*Mucor stolonifer*	Moldy paprika pods
Sauna taker's lung	*Aureobasidium* spp., other sources	Contaminated sauna water
Familial HP	*B. subtilis*	Contaminated wood dust in walls
Wood trimmer's lung	*Rhizopus* spp., *Mucor* spp.	Contaminated wood trimmings
Composter's lung	*T. vulgaris, Aspergillus* spp.	Compost
Basement shower HP	*Epicoccum nigrum*	Mold on unventilated shower
Hot-tub lung	*Cladosporium* spp.	Hot-tub mists, mold on ceiling
Wine maker's lung	*Botrytis cinerea*	Mold on grapes
Woodsman's disease	*Penicillium* spp.	Oak and maple trees
Thatched-roof lung	*Saccharomonospora viridis*	Dead grasses and leaves
Tobacco grower's lung	*Aspergillus* spp.	Tobacco plants
Potato riddler's lung	*Thermophilic actinomycetes, F. rectivirgula, T. vulgaris, Aspergillus* spp.	Moldy hay around potatoes
Summer-type pneumonia	*Trichosporon cutaneum*	Contaminated old houses
Dry rot lung	*Merulius lacrymans*	Rotten wood
Stipatosis	*A. fumigatus, T. actinomycetes*	Esparto dust
Machine operator's lung	*Pseudomonas fluorescens*	Aerosolized metal-working fluid
Amebae		
Humidifier lung	*Naegleria gruberi, Acanthamoeba polyphaga, Acanthamoeba castellani*	Contaminated water
Animal Proteins		
Pigeon breeder's or pigeon fancier's disease	Avian droppings, feathers, serum	Parakeets, budgerigars, pigeons, chickens, turkeys
Pituitary snuff taker's lung	Pituitary snuff	Bovine and porcine pituitary proteins
Fish meal worker's lung	Fish meal	Fish meal dust
Bat lung	Bat serum protein	Bat droppings
Furrier's lung	Animal fur dust	Animal pelts
Animal handler's lung; laboratory worker's lung	Rats, gerbils	Urine, serum, pelts, proteins
Insect Proteins		
Miller's lung	*Sitophilus granarius*	Dust-contaminated grain (i.e., wheat weevil)
Lycoperdonosis	Puffball spores	*Lycoperdon* puffballs
Chemical		
Pauli's reagent alveolitis	Sodium diazobenzene sulfate	Laboratory reagent
Chemical worker's lung	Isocyanates, trimellitic anhydride	Polyurethane foams, spray paints, elastomers, special glues
Vineyard sprayer's lung	Copper sulfate	Bordeaux mixture
Pyrethrum HP	Pyrethrum	Pesticide

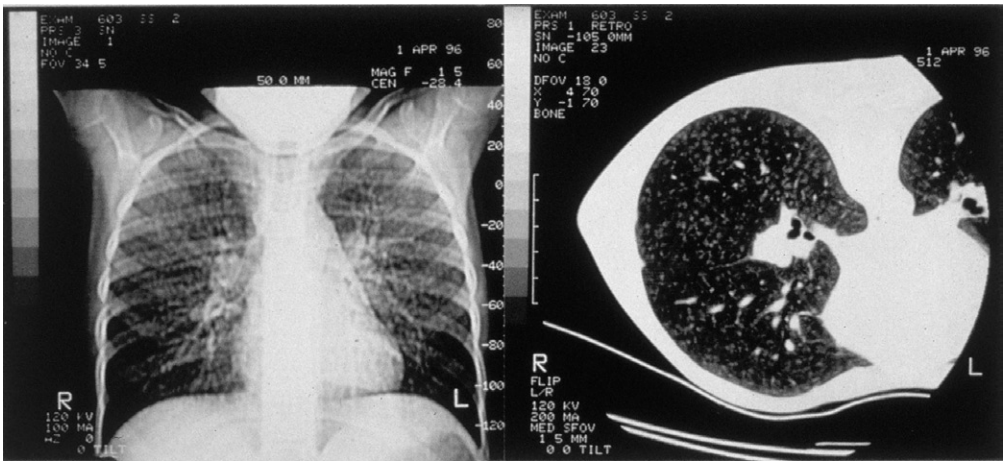

FIGURE 23-1 ■ Hypersensitivity pneumonitis from cockatiel antigens in an adolescent. Chest radiograph shows bilateral reticulonodular infiltrates. HRCT shows diffuse, multiple fine nodules. (Courtesy Robin Deterding, MD, University of Colorado, Denver, CO. From Fan LL. Pediatric interstitial lung disease. In: Schwarz MI, King TE, editors. *Interstitial lung disease*. 4th ed. Hamilton, Ontario: BC Decker; 2003. p. 134–51.)

present in 96 percent (101 of 105), cough was present in 89 percent (102 of 115), weight loss was present in 76 percent (58 of 76), and fever was present in 46 percent (38 of 82). On physical examination, crackles were present in 65 percent (66 of 101) and clubbing was present in 28 percent (19 of 68) of cases. Cough can be productive of thick, clear mucus, and wheezing and rhonchi are sometimes noted on examination, leading to a misdiagnosis of asthma or bronchitis, especially because there may be a partial response to a bronchodilator and temporary clearance of symptoms with systemic corticosteroids.[85]

Diagnosis

Establishing a diagnosis of HP requires maintaining a high index of suspicion, especially when patients have insidious chronic symptoms without episodic febrile illnesses. It is not uncommon that children who are eventually diagnosed with HP will have been treated with inhaled β_2 agonists and corticosteroids before referral.[16] Therefore, consistently taking a careful environmental history is critical to detecting the presence of potential antigens. Compatible findings on pulmonary function testing, HRCT (Fig. 23-1), BAL, and environmental challenge then can aid in establishing the diagnosis. Surgical lung biopsy is usually reserved for atypical or advanced (fibrotic) cases.

Pulmonary function tests typically show a restrictive defect, sometimes with an obstructive component. In reported pediatric cases, the mean (±standard deviation) FEV_1 and FVC in the children tested were 54.3 percent (±19.4) and 52.7 percent (±20.0) predicted. The pressure-volume curve is shifted down and to the right, consistent with decreased compliance. Low lung volumes and diminished diffusion capacity also are present.[32] Although resting room air oxygen saturation may be normal, desaturation with exercise or sleep may occur. With long-standing disease, resting oxygen desaturation can be seen.

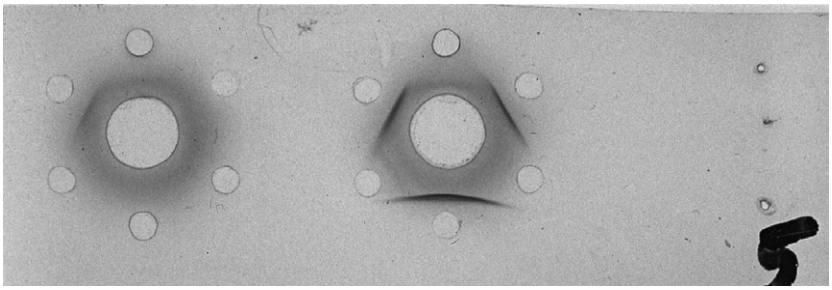

FIGURE 23-2 ■ Serum-precipitating antibodies against cockatiel antigens in the patient shown in Figure 23-1. (Courtesy Robin Deterding, MD, University of Colorado, Denver, CO.)

In the pediatric cases in which oxygenation was documented, 67 percent (64 of 95) had hypoxemia at rest. Pulmonary hypertension may be present with advanced disease, but in contrast to other forms of children's ILD, it may reverse completely with successful treatment.

Classic features of acute HP evident on chest radiography and HRCT include poorly defined centrilobular micronodules, with predominance in the upper and middle lung zones (see Fig. 23-1). On HRCT, widespread ground-glass attenuation and air trapping (especially prominent on expiratory scans) are also characteristic features.[119,162] A small percentage of patients also may have lung cysts.[66] In the more chronic phase, diffuse interstitial infiltrates may predominate, with progression to fibrosis and honeycombing that are indistinguishable from usual interstitial pneumonia.[106] HRCT is much more sensitive for detecting these abnormalities, with the initial plain chest radiographs reported as being normal in up to 37 percent of cases[16] whereas the CT was normal in only up to 2 percent of cases in reported series.[76,119] In the reported pediatric cases of HP, chest radiographs were abnormal at some point in 83 percent (130 of 156).

BAL fluid, obtained by flexible fiberoptic bronchoscopy, typically shows a significant lymphocytosis (>25%),[26] although this is not always present in patients who have insidious chronic disease without superimposed acute episodes.[125,166] In adults, a low CD4/CD8 ratio frequently accompanies the lymphocytosis. Children with HP also have marked lymphocytosis in the BAL compared with healthy pediatric controls (80% vs. 12%), although a low CD4/CD8 ratio may not be as helpful because a low ratio (0.6) is already seen in healthy children without lung disease.[140] Clinicians should be mindful, however, that the presence of BAL lymphocytosis in exposed individuals who are not symptomatic does not predict the development of HP.[38] Induced sputum does not accurately reflect the lymphocytosis seen in BAL and thus cannot be used as an alternative diagnostic step.[48] During an acute episode of HP due to avian antigen, mild BAL neutrophilia and eosinophilia may also be seen in conjunction with the lymphocytosis.[125]

Environmental challenges, in which the patient is returned to the suspected causative environment after having achieved clinical remission (usually through hospitalization or systemic corticosteroid treatment), can be helpful in establishing the exposure basis behind the condition. Signs and symptoms, spirometry, chest radiograph, and inflammatory markers are then followed for decrement. The patient's atopic status must be considered, and these challenges may be difficult to perform in patients without episodic acute manifestations.[85] Provocation challenge performed in controlled laboratory conditions using a specific suspected antigen has been used,[139] but owing to the lack of standardized inhalational antigen preparations, this technique is not routinely recommended.[26] Similarly, measurement of antigen-induced lymphocyte proliferation using lymphocytes gathered from BAL or blood can be a sensitive technique to confirm reaction to a specific antigen, but this test is not widely available.[125,126]

Detecting precipitating IgG antibodies to the suspected offending antigen can be useful in confirming the diagnosis in a patient with documented exposure and typical clinical features (Fig. 23-2). However, most commercial laboratory panels include only certain specific antibodies, so providers must be aware of which are tested before ordering such a panel. Ideally, a sample of the suspected antigen collected directly from the original source is used to test against the patient's serum, but few laboratories can perform this technique. Precipitating antibodies should be sent only in patients who have clinical disease, because 50 percent of individuals who are exposed to a particular antigen develop precipitating antibodies but only a small percentage of these develop HP.[40] Long-term follow-up has shown that the simple presence of precipitins does not increase the likelihood of developing the condition.[38] Conversely, not all individuals with symptomatic HP have positive precipitins for the tested antigens. In reported pediatric cases, positive precipitins were found in 93 percent (134 of 144) of the children tested.

Lung biopsy is typically not necessary for making the diagnosis of HP in the setting of an identified antigen exposure, typical HRCT findings, and positive serum precipitins. However, when clinical picture is atypical or the patient is found to have an undefined ILD on CT, then lung biopsy can be useful in making the diagnosis.[175] Although transbronchial biopsies may sometimes be able to confirm the diagnosis if positive, because of the high potential for sampling error, transthoracic biopsy is usually necessary to obtain tissue to look for the characteristic histologic features described previously (Fig. 23-3). Of the 164 reported pediatric cases of HP, 21 biopsy specimens were obtained and all showed typical histologic changes.

Treatment and Outcome

The mainstay of treatment is eliminating exposure to the offending antigen. However, there can be practical

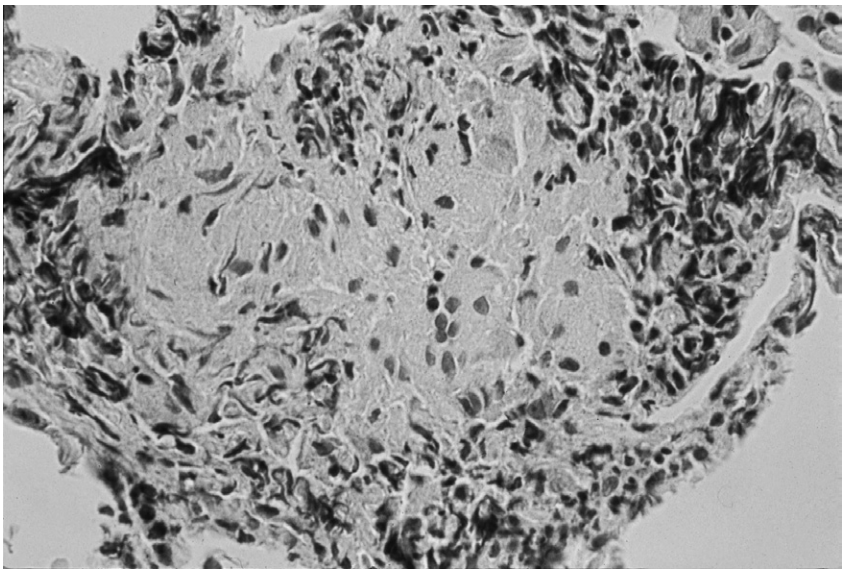

FIGURE 23-3 ■ Transbronchial biopsy specimen from the patient in Figure 23-1 shows a poorly formed granuloma consistent with hypersensitivity pneumonitis. (Courtesy Robin Deterding, MD, University of Colorado, Denver, CO.)

challenges to achieving this goal, especially because even small amounts of exposure can perpetuate the immunologic reaction and, as previously stated, bird antigen in the home environment can persist long after removal of the bird. The presence of markers of poor prognosis, such as traction bronchiectasis and honeycombing on HRCT[185] or fibrosis seen microscopically on a pathologic specimen,[33] would dictate much more aggressive avoidance measures. In the literature, exposure was eliminated in 98 percent of the pediatric cases (106 of 108), with improvement achieved in all but one fatal case.

The use of corticosteroids often results in rapid improvement of symptoms and reversal of radiographic and lung function abnormalities unless irreversible changes in the lung have occurred. Corticosteroids were used in 75 percent (98 of 130) of the reported pediatric cases, with a positive response occurring in all but the one fatal case. Generally, prednisone was given at 0.5 to 2 mg/kg daily for 2 to 4 weeks, followed by tapering of the dosage, although specific regimens have not been studied scientifically. Pulsed methylprednisolone also has been used.[16,30]

The outcome of children with HP, when properly diagnosed and treated, is excellent. In the 130 pediatric cases of HP with reported outcomes, 122 improved or became asymptomatic, 6 patients were still undergoing treatment (including 2 who had experienced relapse), 1 patient's condition remained unchanged, and 1 patient died. In this last case, an 11-year-old girl developed classic features after several years of exposure to budgerigars and other birds.[182] Despite removal of the offending antigens and treatment with corticosteroids and penicillamine, she died of respiratory failure 13 months later. The overall prognosis for children with HP is excellent, provided that a prompt diagnosis is made and appropriate treatment consisting of antigen removal and the judicious use of corticosteroids is instituted.

CHAPTER 24

Complications of Pneumonia

J. Gary Wheeler • Richard F. Jacobs

Most episodes of pneumonia resolve spontaneously or with limited medical therapy. Certain groups, those with underlying diseases, those with anatomic or functional abnormalities, or immunocompromised patients, are more prone to complications, but the normal host is not spared. The most concerning are those who require surgical intervention or prolonged therapy. Guideline development has provided effective management options.[15] This chapter is divided into discussions of empyema lung abscess and other complications (Table 24-1).

EMPYEMA

Collections of fluid in the pleural space have been described in the literature as transudates, pleural

TABLE 24-1 **Major Complications of Pneumonia**

Abscess
Apnea or respiratory failure
Acute respiratory distress syndrome
Atelectasis
Bacteremia and sepsis
Dissemination (skin, solid organs, joints, central nervous system)
Empyema
Hilar adenopathy
Infarction
Necrotizing pneumonia
Pericardial effusion
Pleural effusion
Pneumothorax
Pneumatocoele
Recurrent pneumonia
Pneumothorax
Pericardial effusion

effusions, exudates, purulent pleurisy, parapneumonic effusions, empyema, and complicated empyema. A great deal of inexactitude exists in the use of these terms, and comparing methods of diagnosis and management from one study to another is difficult. The term *transudative pleural effusion* refers to fluid in the pleural space that is a nonpurulent effusion and typically nonpneumonic in origin. The term *purulent effusions* refers to effusions that are more cellular (exudative) and typically pneumonic in origin. The term *empyema* describes purulent effusions with chemical or microbial evidence of a severe process requiring drainage. *Complicated empyema* describes the processes associated with loculations or a fibropurulent rind requiring aggressive manipulations for cure. *Parapneumonic effusion* is a general term referring to any pleural exudative process resulting from an inflammatory process in the lung. Although these definitions are arbitrary and the literature is inconsistent in the use of these terms, a standard approach to the classification of these four types of effusions and their management has evolved.

The first description of parapneumonic infection is attributed to Hippocrates, who in the 4th century BCE advocated incision and drainage of empyema 2 weeks after the onset of symptoms. Since then, the physiology and microbiology of effusions have been described and parapneumonic diseases and the management of fluid collections of the pleural space have been defined. In most cases, the directions of Hippocrates still are relevant: "set him upon a stool, which is not wobbly; someone should hold his hands, then shake him by the shoulders and listen to see on which side a noise is heard. And right at this place—preferably on the left—make an incision, and then it produces death more rarely."[89]

This description of open drainage to normal atmospheric pressures was recognized to be associated with significant mortality rates from hemodynamic instability in 1918, when the Empyema Commission of the United States Army recommended that the practice be abandoned[88]; thereafter, closed-tube drainage was introduced and mortality rates decreased. Developments in radiology, antimicrobials, and surgery resulted in further improvements in care. Today, the major cause of mortality is related to the underlying disease, because the management of parapneumonic effusions in children is largely successful and without residual morbidity. The physician must understand the risks for development of pleural effusion and empyema and indications for thoracentesis, the implications of the results of pleural fluid studies, and the optimal medical and surgical management of the effusions and empyema.

Epidemiology

Parapneumonic effusions are known and expected complications in children with respiratory tract infections. The frequency of effusions may be up to 20 percent of patients with viral or mycoplasmal pneumonia[40,47,124] and 75 percent of patients with proven *Staphylococcus aureus* pneumonia.[8] Empyema has been reported to occur in 6.3 to 23/1000 admissions of children.[97,129] Recent reports suggest rates are increasing.[12,21,122,129]

Pathophysiology

The pleurae are mesodermally derived tissues approximately 30 to 40 μm thick and permeable to liquid and gas.[11,76] The parietal pleurae, which adhere to the chest wall, are fed from the intrathoracic and superior phrenic arteries and have sensory innervation. The visceral pleurae are splanchnic in origin, with blood flow from the pulmonic and pericardiophrenic arteries and no sensory innervation.

Parietal lymphatics absorb most of the excess fluids in pathologic situations and play an important role in normal physiology as well, removing 250 to 500 mL/day in adults.[137] They are the only mechanism for absorbing cells and other debris from the pleura.

The *raison d'être* of the pleural space is unknown. Some mammals do not have a pleural space.[149] In the normal situation, pleural fluid in small amounts is a necessary requirement for optimal lubrication of the pleural space and for mechanical coupling of the lung and chest wall.[76] The accumulation of excess fluid (i.e., effusion) occurs in a limited set of circumstances, through excess production or deficient absorption. Increased production occurs when vessels are leaky (e.g., in septic shock) or active secretion of fluid with mesothelial inflammation (e.g., pleural infection) is present. Decreased absorption occurs with decreased oncotic pressure (e.g., nephrosis), increased pulmonary hydrostatic pressure (e.g., congestive heart failure), or lymphatic obstruction (e.g., malignancy).[152]

The mechanisms behind pleural effusions may vary among different infectious diseases. Effusion can be a "sympathetic" pleural response to a bacterial infection in the lung associated with inflammatory cytokines and altered venous or lymphatic drainage because of local edema. Direct or hematogenous extension of a bacterial process can occur in the pleura. *Mycoplasma* is particularly pathogenic in patients with sickle-cell disease,

TABLE 24-2 Characteristics of Pleural Effusions

Characteristics	Transudative	Purulent Effusion	Empyema	Complicated Empyema
Appearance	Serous	Thin exudate	Turbid	Thick pus
Mean WBC	1000	5300	25,500	55,000
PMN (%)	50	>90	>95	>95
Protein (fluid/serum ratio)	<0.5	>0.5	>0.5	>0.5
LDH (fluid/serum ratio)	<0.6	>0.6	>0.6	>0.6
LDH (IU/L)		>200	>200	>1000
Glucose (mg/dL)	>60	<60	<60	<40
pH*	7.4-7.5	7.35-7.45	7.2-7.35	<7.2
Imaging	Fluid	Fluid	Fluid	Loculations, thick peel, scoliosis

*Should be examined immediately or stored at 0°C (32°F).
LDH, Lactate dehydrogenase; *PMN,* polymorphonuclear neutrophils; *WBC,* white blood cell count.

presumably because of pulmonary sludging, which increases pulmonic venous drainage pressures and results in accumulation of effusions. In pneumococcal disease, effusions often develop several days after the acute infection, when bacteria no longer can be recovered. These effusions may be related to immune complex disease.[18] In patients with tuberculosis, the most common cause of pleural effusions is thought to be the rupture of an old granuloma into the pleural space, with a hypersensitivity response similar to the skin test response,[19] which partly explains the low yield in cultures.

After an inflammatory process is initiated, it tends to progress through three classic stages. The first, defined as a *purulent effusion*, is the acute exudative stage, with a thin pleural exudate characterized by normal glucose, lactate dehydrogenase (LDH), and pH. The second transitional fibropurulent stage, categorized as *empyema*, is characterized by turbid fluid, decreased glucose concentration (<60 mg/dL) and pH (7.2 to 7.35), and elevated LDH (>200 U/L). The third chronic organizing stage is notable for a very low pH (<7.2) and glucose level (<40 mg/dL), LDH concentration greater than 1000 U/L, and development of loculations and peel. This fluid is found in patients with *complicated empyema*. Intervening early (<4 days) before the organizational stages of disease has been proposed to lead to a better prognosis.[64]

Analysis of the pleural fluid is most helpful when the underlying disease is unknown or when a primary pulmonic process is suspected. When patients have effusions caused by hydrostatic imbalance, the effusion is a transudate. Its protein and cell count do not exceed the range of normal pleural fluid (5000 cells/mm^3 and <2 g of protein).[8,137] Patients who have an active inflammatory process may have an exudate, defined by excess protein and cells. In children, the most common cause of exudative pleural processes is pneumonia. In adults, most pleural effusions are related to congestive heart failure or malignancy,[83] but pneumonia is the most common cause of empyema.[110] Table 24-2 summarizes the general differences among pleural effusions.

Table 24-3 lists causes of effusions. Some of these causes, particularly iatrogenic causes, such as invasive procedures and drugs, are important to consider in the differential diagnosis of a difficult case. Others are associated with specific syndromes, such as acute respiratory distress syndrome[140] and yellow nail lymphedema syndrome.[143] Motor vehicle accidents have been identified as a common cause of serosanguineous effusions when disruption of normal mechanical lung function and hematoma occur.[120]

TABLE 24-3 Causes of Pleural Effusion

- Capillary leak
- Sepsis syndrome
  - Vasculitis associated with immune complex disease
    - Connective tissue diseases
    - Inflammatory bowel disease
  - Malignancy (lymphoreticular, sarcoma, neuroblastoma)
  - Toxins (e.g., TSST-1)
  - Drugs (amiodarone, bleomycin, isoniazid, methotrexate, nitrofurantoin, phenytoin)
  - Myxedema
  - Trauma
- Increased hydrostatic pressure
  - Congestive heart failure
  - Sickle-cell disease
  - Pulmonary venous hypertension
  - Superior vena cava syndrome
  - Pregnancy
- Decreased oncotic pressure
  - Nephrosis
  - Cirrhosis
  - Protein malnutrition
- Obstructed lymphatics
  - Congenital lymphangiectasia
  - Yellow nail syndrome
  - Radiation injury
  - Neoplasia (metastatic disease)
- Pleural inflammation
  - Pneumonia
  - Lung abscess with pleural fistula
  - Pleural infection (e.g., tuberculosis)
  - Esophageal rupture
  - Pancreatitis
- Iatrogenic
  - Drugs
  - Central line misplacement

TSST-1, Toxic shock syndrome toxin–1.

Microbiology

Among children with parapneumonic effusions, no prospective study has established firmly the frequency with which effusions occur and how many are associated with particular microbes. Although respiratory viruses infrequently cause symptomatic effusions, the sheer number of cases and the presence of asymptomatic cases likely would implicate viral infection as the most common cause. Definite viral disease has been associated with cytomegalovirus, Epstein-Barr virus, measles, and adenovirus.[42,43,66,96] Other pathogens, such as *Mycoplasma* and *Chlamydia*, are difficult to diagnose but may account for a significant number of pneumonic infections in older children and adolescents.[40,43] Viral, mycoplasmal, and chlamydial organisms rarely are identified in patients with effusions requiring intervention.

The bacteriology of empyema is constantly evolving. Several past articles have established the role of various bacterial pathogens in childhood effusions. A study of 227 children by Freij and colleagues[42] published in 1984 found *S. aureus* (29%), *Streptococcus pneumoniae* (22%), and *Haemophilus influenzae* (18%) to be the three most frequent causes of parapneumonic effusions (see Table 24-3). Subsequent studies show that the frequency of these pathogens has been affected by vaccine[1,20] and antibiotic use. Pathogen frequency in different eras is shown in Table 24-4. *H. influenzae* and *S. pneumoniae* vaccines have led to a decreased incidence of vaccine-specific strains as a cause of empyema, whereas methicillin-resistant *S. aureus* (MRSA) has emerged as a frequent cause of community-acquired disease, with rates in Texas doubling from 2001 to 2009.[24,129] Among cases of *S. pneumoniae* infections, nonvaccine strains are increasing in number and severity.[20,35] Recent studies using a U.S. national hospital discharge database suggest that *S. pneumoniae* remains the most common etiology of bacterial empyema.[46] Certain groups of children (e.g., neonates,[42] immunocompromised hosts, patients with preexisting chest tubes that become infected with nosocomial pathogens, patients with a ruptured viscus, and patients with foreign body aspiration) are at higher risk for acquiring gram-negative infections.[12]

Administration of antibiotics before the diagnosis of empyema is made influences the recovery of organisms. In one report, the incidence of prethoracentesis antibiotics was 71 percent in culture-negative effusions and only 41 percent in culture-positive effusions.[57] Pretreatment with antibiotics may be associated with a decrease in the number of positive blood cultures and in the number of patients from whom *S. pneumoniae* isolates are recovered.[110] Freij and associates[42] reported the frequency of parapneumonic effusions occurring in children with pneumonia caused by specific pathogens. The rates of effusion by organism were as follows: group A streptococcus, 86 to 91 percent; *S. aureus*, 72 to 76 percent; *S. pneumoniae*, 57 percent; *H. influenzae*, 49 to 75 percent; *Mycoplasma*, 21 percent; and adenoviruses, 11 to 33 percent.

Anaerobes were sought carefully by Brook and Frazier,[17] who found them infrequently in patients younger than 6 years of age. The anaerobes rarely were found in patients with primary pneumonia, occurring most often in patients with lung abscess and aspiration pneumonia.[17] In older patients (7 to 17 years old), anaerobes were recovered as isolated pathogens in 44 percent of cases.[17] Virtually every bacterial organism has been associated with pleural effusion at one time or another. *Brucella*,[69] *Francisella tularensis*,[121] and *Yersinia enterocolitica*[65] may be associated with the development of pleural effusions. The diagnosis in such cases often is suggested by a unique history in the patient.

Mycobacterial effusions are uncommon in U.S. children but are well described. In four published reviews, only two patients (from Nigeria) were reported to have *Mycobacterium tuberculosis*.[42,57,90,96] In a series of 303 children younger than 2 years of age with tuberculosis, 3.3 percent had an effusion.[54] In adolescents with tuberculosis, the incidence of effusion likely approximates that of adult disease. In one series of adult patients with primary tuberculous disease, pleural effusion occurred in 29 percent of cases.[29] In another adult series, primarily of reactivation disease, pleural effusion occurred in 1 percent of the patients.[48] Whether coinfection with human immunodeficiency virus (HIV) is increasing the incidence of effusion is controversial.[39]

Histoplasmosis has been associated with pleural effusion in 0 to 6 percent of childhood histoplasmosis cases.[112] Blastomycosis has been associated with pleural effusions in 0 to 40 percent of cases.[111,137] Effusions resulting from other fungi (e.g., *Coccidioides*, *Aspergillus*) have been described.[88] Parasitic diseases manifesting with effusions

are uncommon but are found in patients with *Entamoeba histolytica* disease, most often from rupture of a hepatic abscess into the pleural space.[88] Echinococcal disease also has been reported.[41]

Pleural effusion associated with adult HIV infection has been reported in 14.6 percent of hospital admissions in one series in which 67 of 160 cases were infectious. Of those cases, 50 were associated with bacterial pneumonia, 10 with tuberculosis, and 5 with *Pneumocystis jiroveci* pneumonia.[2] Another report on patients infected with HIV suggested that empyema was seen primarily in patients with intravenous drug abuse.[56] We have not seen empyema in our pediatric HIV-infected patients, perhaps because of the more recent use of more effective antiretroviral therapy.

Drug resistance in community-acquired pneumonia complicates the management of parapneumonic effusions. Intermediate or fully resistant *S. pneumoniae* was found in 12.8 percent and 10.1 percent of isolates in a study from multiple pediatric centers from 1993 to 2000; 7.5 percent were cephalosporin-resistant.[142] MRSA is a growing concern in empyema. Reports since 2000 have shown that 22 to 78 percent of isolates of *S. aureus* were methicillin-resistant, with many being community acquired.[61]

Diagnosis

Clinical Presentation

Symptoms most specific for parapneumonic processes are dyspnea and pleuritic pain. Dyspnea occurs when the volume of the effusion mechanically interferes with breathing or when pain prevents adequate gas exchange. Pain occurs with irritation of the parietal pleura and on inspiration (i.e., pleurisy). Fever is generated by the inflammatory response and pathogen-specific components (e.g., lipopolysaccharide, toxins). With an acute bacterial process, the fever can be high and hectic, mimicking the fever that occurs with an abscess. Patients in the chronic organizational phase generally have less fever. Cough and malaise are secondary symptoms. Hemoptysis and purulent sputum also may occur. The onset of symptoms of a purulent effusion may be delayed in time and distinct from the symptoms found at the onset of the pneumonia in older children; infants usually have no symptom-free period[19]; in the early phases of effusions, the patient may have no symptoms.

The physical examination usually is revealing. The child is tachypneic in more than 70 percent of cases, but breathing is shallow as a result of the child's attempt to minimize pain. Fever and cough usually occur in more than 90 percent of patients with purulent effusions.[90] The patient may appear toxic, with acute infection. Patients often posture toward the affected side. Classically, auscultation reveals a decrease in breath sounds and occasionally detects a pleural rub, but pleural rubs often are absent in a very young child. Rales from an associated pneumonia may be heard. Depending on the stage of the process, percussion may reveal a level of dullness associated with free-flowing effusion. As the process organizes, it may be less evident. Empyemas can erode through the chest wall into the subcutaneous tissue (i.e., empyema necessitatis) or into a bronchus (i.e., bronchopleural fistula).

Imaging

The diagnosis most often is made by radiographic examination of the chest. Consolidation of a lobe of the lung is present, with an effusion obscuring the diaphragm. A standard posteroanterior standing view reveals blunting of the costal diaphragmatic gutter. As fluid tracks along the lateral and posterior chest wall, a meniscus configuration is seen. Distinguishing it from pleural thickening may be difficult, and in such cases, a decubitus or cross-table view of the chest allows free-flowing fluid to layer out on the dependent chest wall. In older children and adults, a decubitus layer of fluid of more than 10 mm is considered a sufficient volume of fluid to attempt to extract by thoracentesis.[15,82] With large volumes of fluid (>1000 mL),[123] compression of the lung and shift of the trachea away from the effusion (Figure 24-1) may occur. As an empyema develops and organizes, discrete pockets of fluid (i.e., loculations) may form within the pleural cavity (Figure 24-1C). Occasionally, loculations are confused with lung abscess. Scoliosis also is well defined by the chest radiograph and occasionally is used as an indication for surgery.[57] The observation of an air-fluid level in the pleural space signifies that air has been generated in the pleural space by gas-forming organisms or has entered through a pneumothorax, perforated viscus, or bronchopleural fistula.

Ultrasonography has shown great utility in providing better guidance for thoracentesis of pleural fluid. It is noninvasive, without ionizing radiation, allows empyema to be defined by showing internal echoes and septations (Figure 24-2),[130,153] and is the imaging mode of choice for most pleural effusions.[22,103] Transudates uniformly are anechoic, although approximately one third of exudates also are anechoic.[153] Ultrasonography is not as precise as computed tomography (CT) in differentiating a lung abscess from an empyema. CT and magnetic resonance imaging occasionally are required to distinguish parenchymal from pleural disease, identify a nonopaque foreign body, or locate a fistula.[139] CT particularly is useful in a patient whose chest radiograph shows total opacification of the lung, and thus is considered by some physicians the study of choice in this situation.[57] Ultrasound can have false-negative results, and CT can have false-positive findings on examination of pleural effusions. One study of adults showed that neither ultrasound nor CT effectively predicted the stage of the effusion or predicted the surgical outcome.[67]

Pleural Fluid Analysis

Thoracentesis can play an important role in the management of parapneumonic effusions. Fluid should be obtained from the pleural cavity if the fluid is adequate in volume and anatomically accessible, if a microbial diagnosis has not been made or presumed, and if antibiotic therapy is intended or if pulmonary function is compromised by the effusion and imaging does not reveal

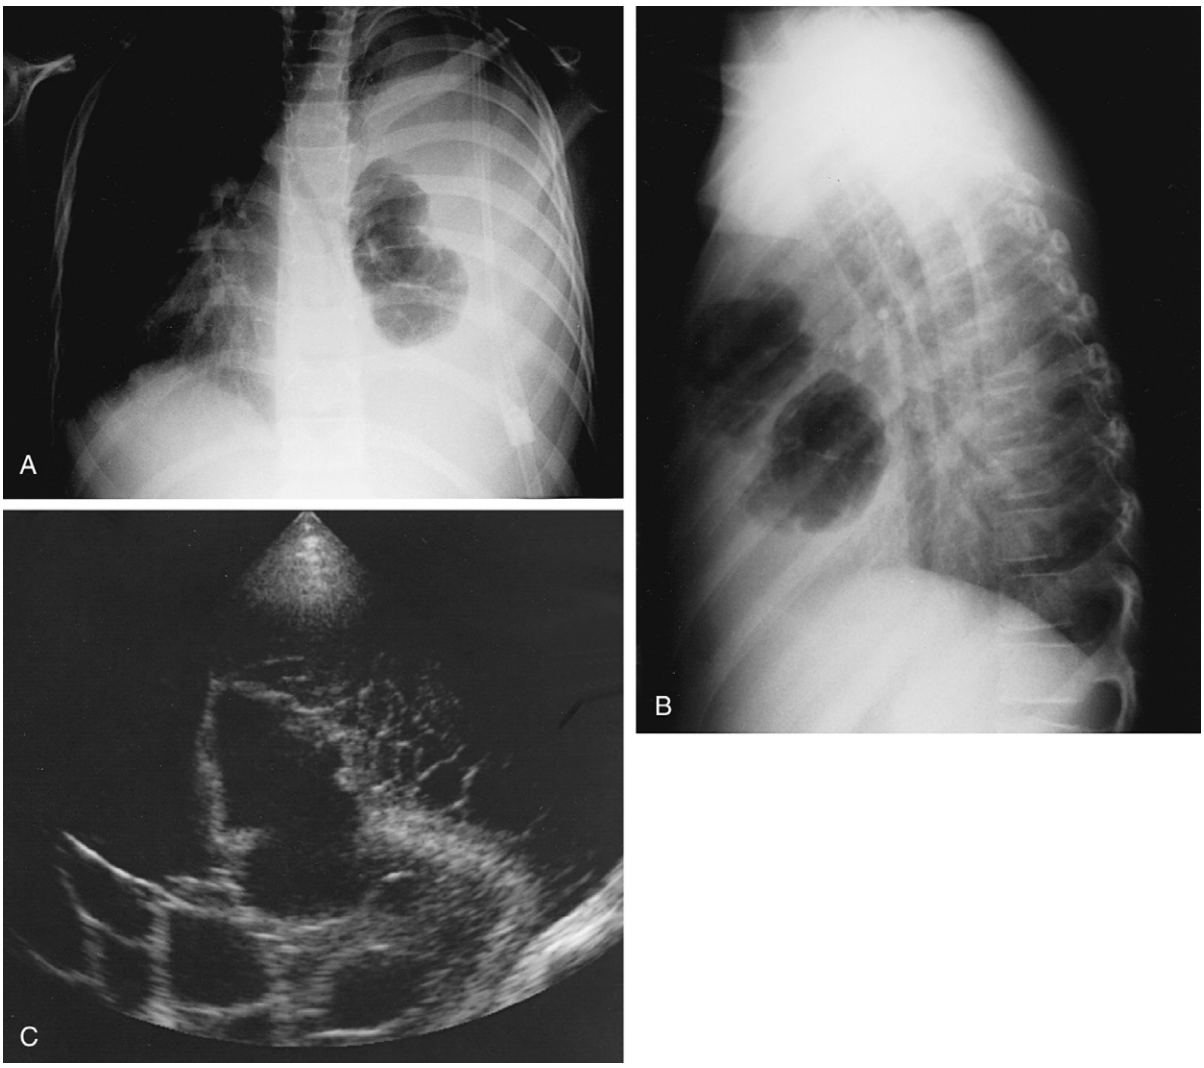

FIGURE 24-1 ■ A-C, Chest radiograph and ultrasound examination images from a 7-year-old boy with a 5-day history of vomiting, diarrhea, and low-grade fever. He had a history of varicella 2 weeks earlier. The patient was hospitalized for dehydration and developed left-sided chest pain and a mild cough. Intravenous nafcillin was begun, but his condition deteriorated over the next 4 days, with an enlarging effusion and tracheal shift. Loculations were found on ultrasound **(C)**. He had a thoracotomy performed on day 6 with decortication and removal of a fibrinous rind. The patient was afebrile within 24 hours and received 1 week of intravenous antibiotics and 1 week of oral antibiotics. He was well on follow-up examination after discharge.

evidence of organization to determine whether further intervention is necessary.

The volume and location of the fluid can be determined precisely by ultrasound examination. When a healthy child has a small pleural effusion, thoracentesis usually is not required because small effusions generally can resorb. Thoracentesis for microbiological diagnosis can often be avoided, because a 10 to 50 percent chance of recovering the etiologic organism from blood cultures exists in empyema.[6,42] We suggest, however, that when the clinical presentation is atypical or a moderately sized effusion exists, thoracentesis usually is indicated to define the microbial process. Atypical situations include a history of trauma, foreign body aspiration, prolonged or chronic disease, and underlying systemic diseases (e.g., congestive heart failure, malignancy).

In a classic article published in 1972, Light and associates[83] established the methodology by which transudates could be differentiated from exudates. Such criteria are valuable in determining whether antibiotic treatment is indicated, particularly in patients with underlying diseases that predispose them to sterile effusions but who may have a comorbid infectious condition. An exudate was defined by any of the following criteria: a fluid-to-serum protein ratio greater than 0.5, an LDH fluid-to-serum ratio greater than 0.6, a glucose concentration less than 50 mg/dL, or a pH less than 7.2. This study was based on the results from 150 adult patients, 103 of whom had exudates.[83] Modifications of Light's criteria have been made by reducing the LDH ratio threshold to 0.45.[55] A two-step process has been recommended to separate transudates from exudates using only the protein and LDH serum-to-fluid ratios in the initial evaluation. If a patient had an apparent exudate, additional studies, including cultures, stains, pH, and glucose, are indicated.[107]

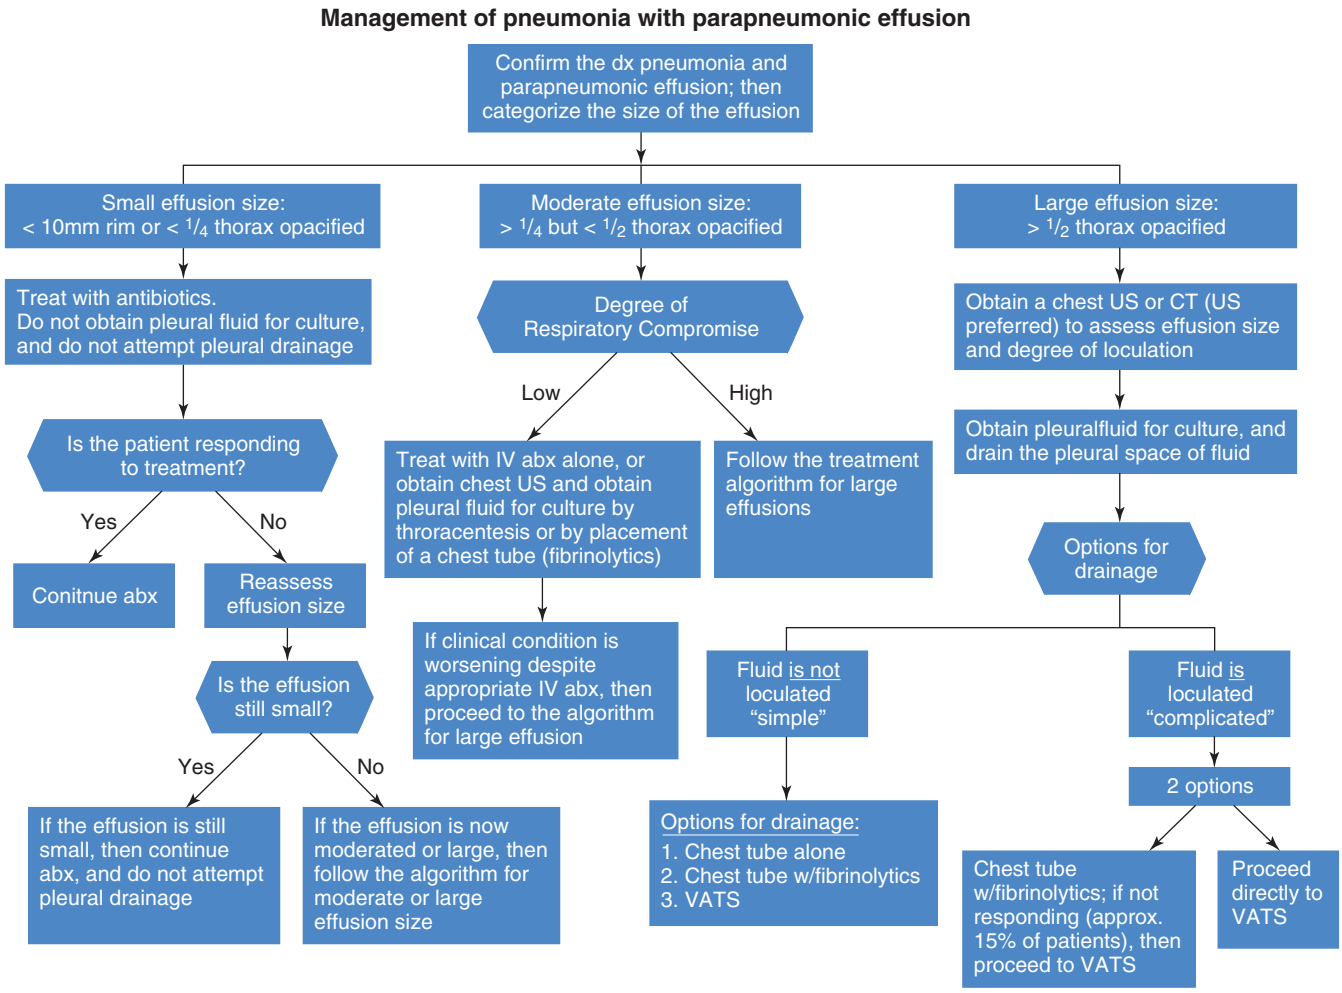

FIGURE 24-2 ■ Algorithm for the management of pneumonia with parapneumonic effusion from the IDSA guidelines.[15] *CT,* Computed tomography; *US,* ultrasound; *VATS,* video-assisted thoracic surgery. (See companion website on Expert Consult for a color version of this figure.) (From: Bradley JS, Byington CL, Shah SS, et al. The management of community-acquired pneumonia in infants and children older than 3 months of age: clinical practice guidelines by the Pediatric Infectious Diseases Society and the Infectious Diseases Society of America. *Clin Infect Dis* 2011;**53**:e25–76.)

The application of these criteria to children has received limited study. In one series of 61 children, patients who required chest tubes or decortication had a mean pleural fluid pH of 7.24 or 7.10 in contrast to children who were treated with antibiotics only (pH 7.35). The mean pleural fluid glucose concentration was 74 g/L in the group treated with antibiotics, 10 g/L in the group treated with chest tubes, and 24 g/L in the group treated by decortication.[57] Another, more recent study confirmed that a pH less than 7.2 and low glucose concentration were predictors of reintervention.[98] The role of this analysis has been questioned and new Infectious Diseases Society of America (IDSA) guidelines for children do not recommend glucose, LDH, and pH studies because they rarely modify patient management.[15]

Standard Gram stain and bacterial culture (aerobic and anaerobic) are indicated when thoracentesis is performed in patients in whom diagnosis of infection is considered. The Gram stain often is positive in patients with bacterial infections and may be used to direct empirical therapy until culture or polymerase chain reaction (PCR) results are known. In one study of children, 12 of 54 sterile effusions from patients with negative blood cultures had a positive Gram stain.[42] Some experts consider that a positive Gram stain indicates a more severe process and that such patients are more likely to require more invasive surgical procedures.[19]

The total white blood cell count in empyema fluid can vary from 5000 to 625,000 cells/mm^3, with median values ranging from 5000 to 55,000 cells/mm^3.[42,57] Virtually all cells are neutrophils in bacterial infections. Marked eosinophilia may be seen in parasitic, fungal, tuberculous, or hypersensitivity disease and when blood is found in the pleural space.[19] Numerous small lymphocytes suggest malignancy, tularemia, or tuberculosis.[38,51,107,153] Other studies are required when the history suggests another underlying process. When tuberculosis is suspected by history, specific mycobacterial stains and cultures should be obtained. Identification of mycobacteria by stain and culture may be equivalent to the rate of identification of the disease process by pleural biopsy (approximately 25%).[102] Specific mycobacterial and fungal stains also should be obtained using a Ziehl-Neelsen/auramine stain and potassium hydroxide. Application of newer methods

for diagnosis, such as PCR and tuberculostearic acid by mass spectroscopy, may be indicated.

When malignancy or metastases are suspected, cytology is necessary.[51] Most effusions in children that prove to be malignant are of lymphoreticular origin. Amylase sometimes is measured and is elevated in cases of esophageal rupture, acute hemorrhagic pancreatitis, or pulmonary infarction.[81,123]

Molecular diagnostics is bringing promising advances to the bacteriologic diagnosis of empyema. PCR technology has been compared with routine culture and bacterial antigen and has shown increased sensitivity and good specificity for the diagnosis of *S. pneumoniae* with 16S rDNA or MRSA using the mec-300 gene probe.[35,122] In recently reported studies,[12,100] the sensitivity of PCR has been greater than 80 percent. Turnaround times can be quite rapid, exceeding traditional culture methods. The sensitivity of PCR for tuberculous effusions ranges from 20 to 81 percent, and specificity ranges from 78 to 100 percent.[39] New commercially available PCR cocktails for respiratory viruses are also available but because of current expense are best reserved for difficult or critically ill patients.

Additional Diagnostic Studies

An intradermal test should be applied to any child with a parapneumonic effusion to evaluate tuberculosis as a possible cause. One third of patients with tuberculous effusions have a negative purified protein derivative skin test result.[10] Early morning gastric aspirates have been recommended if tuberculosis is suspected but tuberculosis-specific interferon-γ release assays are now approved for children down to 5 years of age. Sensitivity and specificity remain problematic, however.[87,145] Bacterial blood cultures also are indicated because one third of patients can have positive blood cultures and negative pleural fluid Gram stain and culture results.[42] Sputum is a less reliable source from which to determine the microbial cause of an effusion but may be helpful in an older patient with purulent sputum and a single predominant organism. Sputum can be diagnostic in older children with reactivation or cavitary tuberculosis and in cases of blastomycosis and histoplasmosis. Cold agglutinins or *Mycoplasma* serology may confirm the cause of a pleural effusion, although the nonspecificity of cold agglutinins and the delay in the increase in antibody titers render these data of marginal use in the acute management of the patient. Viral cultures are useful in only the more unusual cases and generally provide information that is not helpful in the initial management of the patient. Rapid diagnostic antigen assays, such as the rapid tests for influenza A and B and other respiratory viruses, may be useful in defining the primary cause of respiratory disease but do not help exclude secondary bacterial pathogens causing pneumonia and a parapneumonic effusion. When other diseases, such as Wegener granulomatosis[7] and systemic lupus erythematosus, are suspected, disease-specific tests such as antineutrophil cytoplasmic antibody and antinucleic acid antibody are indicated.

Management

If a patient has an underlying disease process associated with pleural effusion and thoracentesis has excluded bacterial infection (e.g., normal protein and LDH fluid-to-serum ratio, normal glucose level, negative cultures, and Gram stain results), no further treatment is indicated other than treatment of the underlying disease. These patients continue to be at risk for developing infection of the effusion and may require repeat examination of pleural fluid later if infection is suggested clinically.

If a purulent effusion is suggested by imaging, thoracentesis, or surgical findings, empirical antibiotic therapy is indicated. Pathogens of most importance are *S. pneumoniae*, *S. aureus*, and *Streptococcus pyogenes*. Empirical therapy choices are changing as drug resistance patterns continue to change, immunization against *H. influenzae* type b and *S. pneumoniae* has become widespread, and the ability to make a rapid diagnosis (e.g., PCR) improves. For mildly ill patients, amoxicillin orally or penicillin or ampicillin intravenously can be used. For patients who are moderately ill, unimmunized, or allergic to penicillin or in whom *S. aureus* is suspected (because of past disease or presence of pneumatocoele), clindamycin in combination with cefotaxime is used. Vancomycin is substituted for clindamycin in critically ill patients.

Ticarcillin-clavulanate, imipenem-cilastatin, meropenem, and piperacillin-tazobactam are alternatives in nosocomial infections, gram-negative risk (neonates and postsurgical cases) or if anaerobes are considered, particularly if aspiration is thought to play a role, such as in patients with abnormal swallowing. Aminoglycosides are alternatives for proven gram-negative infections, and cefepime is helpful in nosocomial pneumonia and empyema because of its current efficacy for *Enterobacter* spp. In patients with renal failure or cephalosporin hypersensitivity, aztreonam is effective therapy for gram-negative infections. Ceftazidime or cefepime, broad-spectrum β-lactams with or without a β-lactamase inhibitor (i.e., ticarcillin–clavulanic acid, imipenem cilastatin, meropenem, or piperacillin-tazobactam), or aminoglycosides are indicated for *Pseudomonas* infection.

Surgical drainage is considered a crucial factor in resolving anaerobic infection. Clindamycin and metronidazole are effective, particularly when postsurgical infection or a ruptured gastrointestinal viscus is present. Upper respiratory tract anaerobes may be resistant to penicillins because of β-lactamase–producing oral flora (particularly *Prevotella* and *Porphyromonas* spp.).[17] In these situations, penicillin sensitivity should be documented before a penicillin is used as primary therapy.

Once a pathogen is isolated and sensitivity patterns are established, therapy may need to be modified. Past studies have suggested that resistant isolates of pneumococcus were treated effectively with parenteral penicillin in high doses.[16,17,77,105] Further, in 2008, the Clinical Laboratory Standards Institute (CLSI) issued new standards for resistance. The net effect was to reduce the number of isolates in the community with any resistance from approximately 25 percent to 7 percent.[25] New guidelines for pediatrics now recommend amoxicillin orally or penicillin or

ampicillin intravenously for *S. pneumoniae*–associated community-acquired pneumonia with a minimum inhibitory concentration (MIC) 2 μg/mL or less. When the pneumococcus is highly resistant to penicillin (>4 μg/mL), ceftriaxone is preferred, with levofloxacin, linezolid, clindamycin, and vancomycin considered alternatives.[15] New guidelines for management of MRSA were published by the IDSA in 2011.[84] These suggest that vancomycin is still the preferred treatment. The guidelines for adults suggest a nonvancomycin regimen for disease associated with an MIC greater than 2.0 μg/mL. A recent report notes, however, that a poor clinical outcome may be independent of antibiotic choice and directly related to an MIC greater than 1.5 μg/mL.[59] Clindamycin or linezolid may be considered for treatment of MRSA but is discouraged as monotherapy if the patient is bacteremic. Clindamycin sensitivity should be determined, because many MRSA and methicillin-susceptible *S. aureus* isolates are resistant to clindamycin.[128] Susceptibility should be confirmed with performance of a "D" test. Intravenous clindamycin can be switched to oral clindamycin later in the clinical course, offering a management advantage over vancomycin. New drugs such as linezolid are in limited use at this time because of high cost and some side effects, such as neuropathy and visual changes, that may be hard to monitor in small children. Daptomycin is specifically avoided in the lung because of its inactivation by surfactant.

With appropriate antibiotic therapy, the duration of fever in uncomplicated cases of purulent effusions usually is less than 48 to 72 hours.[101] When fever persists beyond 72 hours, surgical drainage may be required. The duration of antibiotic therapy is based on the response of the patient to the medical and surgical therapy provided. In one series of pediatric patients, the total duration of antibiotic therapy for patients with severe pleural infections who did or did not have surgical drainage was comparable (approximately every 12 days).[57] The duration of combined intravenous and oral therapy was 12 to 24 days in the study reported by Freij and associates,[42] with patients with *S. pneumoniae* infection receiving the shortest courses of antibiotic therapy and patients infected with *S. aureus* being treated for longer periods. A prudent standard is to continue treatment for a minimum of 1 week beyond the last febrile day.

Drainage of the pleural space has been the standard treatment of parapneumonic effusions in four classes of patients: (1) patients in whom thick, purulent material is found at thoracentesis; (2) patients with a pleural fluid pH level less than 7.35 and glucose level less than 60 mg/dL; (3) patients for whom antibiotic therapy has not been associated with a timely clinical response (72 hours); and (4) patients in whom pulmonary function is compromised, as shown by severe hypoxemia or hypercapnia. The chest tube is placed until minimal drainage is noted (usually <50 mL/day).[36]

When closed-chest-tube drainage is not associated with clinical improvement and defervescence, if the lung parenchyma is trapped by the fibrinopurulent peel, or fever persists, video-assisted thoracoscopic surgery (VATS) or decortication often is required. If the pleural involvement is limited, a small incision (mini-thoracotomy) can be employed.[113] Ultrasonography and CT are required to define these conditions. Decortication is rarely performed now but has shown comparable hospital length of stay to that with chest tube drainage with minimal morbidity.[44,57] Decortication seems to have an advantage in advanced disease in which fibrosis in the pleural cavity has resulted in a large peel.

Although general anesthesia is required for VATS, only two small incisions are needed—one through the existing chest tube tract for a telescope and the second through which operating instruments are passed. This procedure allows adhesiolysis and débridement and should be performed before a thick peel develops. Proponents of VATS argue that a brief operative procedure and the attendant risks of anesthesia outweigh the child's discomfort during thoracentesis (and chest tube placement) and postoperatively. More importantly, a definitive procedure is done, rather than running the risk of having to perform subsequent chest tube placements and thoracotomy. The hospital stay is shortened. VATS is more commonly performed than closed-tube drainage at this time, with some evidence for shorter length of stay.[68,70,127] Doski and colleagues[34] reported a series of 139 children who were studied from 1992 to 1998. By comparing historical cohorts, they showed a shorter length of stay (7 days vs. 11 and 12 days) for children who underwent VATS than for groups of children who had thoracentesis, chest tube drainage, or fibrinolytic therapy and rescue VATS for failure. Of 98 patients who received traditional therapy, 12 required thoracotomy, in contrast to none in the primary VATS group. A small, randomized study of 20 patients was conducted from 1994 to 1996 and showed that VATS was superior to chest tube drainage with fibrinolytic therapy. Compared with chest-tube drainage with fibrinolytic therapy, VATS resulted in a higher primary success rate (91% vs. 44%), fewer hospital days (8.7 vs. 12.8 days), and lower costs (approximately $16,000 vs. $24,000).[147] Another randomized study in 18 children showed VATS superior to chest tube drainage,[75] whereas a larger randomized study of 60 children showed VATS comparable to chest tube drainage with urokinase.[136] Other studies have shown similar mixed results.[45,67,95,115]

The use of radiologist-directed thoracentesis with pigtail catheters (smaller bore than standard chest tubes) for drainage with fibrinolytic therapy has been promoted as a way to reduce the number of operative procedures and achieve shorter hospital stays; it has produced good results in children.[3,119] This therapy may have value in patients with organizing pleural inflammation and inadequate drainage caused by loculations of pleural fluid without a peel.

The use of streptokinase in children with pleural effusion was reported in 1993.[119] The occasional side effects caused by streptokinase reported in adults have generated concern about its safety instead,[13] and its utility has been challenged in adults in a randomized study showing no benefit.[91] Urokinase is less expensive than streptokinase and has been used in children with minimal adverse effects.[53,71,118,139] In adults and children, these different agents seem to be equivalent,[6,14] although commercial shortages of the products have occurred. The tissue-type

plasminogen activator alteplase is the fibrinolytic therapy most commonly used at this time. It is less likely to promote allergic reactions and has a low risk for bleeding complications.[9] Reports have questioned the benefits of interventional radiologist-placed catheters with fibrinolytics for empyema.[117] A meta-analysis of eight evaluable reports from 2000 to 2004 of operative and nonoperative approaches to empyema suggested that the failure of primary therapy was intermediate for fibrinolytic therapy (9.4%), in contrast to simple chest tube drainage (23.6%) and either VATS (2.8%) or thoracotomy (3.1%).[5] A newer review identified only two randomized, controlled trials comparing intrapleural fibrinolytic therapy with VATS and showed no difference.[73] The British Thoracic Society published clinical guidelines[6] for management and concluded that fibrinolytic therapy shortened the hospital stay, but that failure should prompt early consideration of thoracic surgery. Rarely are full thoracotomy and pneumonectomy required for severe pneumonic and parapneumonic disease.

The IDSA put forth consensus guidelines for clinicians for the management of pneumonia and effusions in 2011.[15] Figure 24-2 is an algorithm from the guideline incorporating alternatives for the management of pleural collections. Other comparable guidelines exist,[62,108] but all emphasize the importance of local expertise and the emphasis on the individual circumstance of the patient. A large retrospective review with multivariable analysis of 40 pediatric hospitals using the Pediatric Health Information Systems showed no difference in VATS, CT with fibrinolysis, CT without fibrinolysis, or thoracotomy for length of stay and only marginal differences in cost. VATS was associated with fewer additional procedures.[132] Some emphasize the importance of early versus late operative strategies[62] and another structured review determined that early operative procedures did shorten hospital stay.[126]

In cases of chronic empyema, other approaches are used. A closed tube can be converted into an open drainage tube. This conversion is accomplished safely a minimum of 10 to 14 days into the course of an empyema when the visceral and parietal pleurae fuse, and a pneumothorax can be avoided safely.[88] Other options include open drainage by rib resection and creation of a pleural window. The window ultimately closes with lung expansion and granulation, with disappearance of the pleural space.

One frequent cause of bloody pleural effusions is motor vehicle accidents.[88,120] In one series of 100 children, 56 percent had pleural effusions associated with pulmonary contusions. They were treated with closed-chest-tube drainage; no antibiotics were used, and no infectious complications occurred.[120] Management of pleural hematoma secondary to trauma occasionally is complicated by infection because the bloody pleural fluid is an excellent growth medium. One study suggested that empyema is less common in posttraumatic effusion with closed-chest-tube drainage than in repeated thoracentesis.[146]

Prevention of empyema is theoretically improved by the use of vaccines against *S. pneumoniae*, the most common associated agent. One comprehensive study using national data showed an actual increase of 70 percent in empyema hospitalizations from 1997 to 2006, when the 7-valent pneumococcal vaccine was implemented.[79] At the same time, invasive pneumococcal disease rates decreased. The impact of the new 13-valent pneumococcal vaccine is not yet known.

Prognosis and Long-Term Outcome

The long-term outcome of patients with effusions depends on the underlying cause. Patients with empyema or necrotizing pneumonia who previously were well recover satisfactorily in most cases.[125] Complications from closed-chest-tube drainage include bleeding, infection of the exit wound, bronchopleural fistula, and laceration of the lung. Because of these rare complications, chest tube placement, performed in the past by the pediatrician, now is delegated more frequently to the surgeon. Other rare complications, such as temporary paralysis of the diaphragm, have been reported.[97] In three retrospective reviews, the percentage of patients who required closed-chest-tube drainage or other surgical procedures ranged from 62 to 80 percent.[42,57,97] The rate of decortication ranged from 4 to 43 percent.[42,57] The immediate mortality rate for children in recent years has been 0 to 10.8 percent.[42,57,90,97] In one of these studies, the mortality rate was highest for children younger than 1 year old.[42] Studies conducted to evaluate long-term, specific pulmonary disability using pulmonary function tests and lung volumes have shown normalization of these study results over time.[42]

LUNG ABSCESS

A lung abscess is distinguished by liquefaction and destruction of parenchymal tissue, organization, and cavitation. Necrotizing pneumonia, which on imaging lacks the "rim" representing the organization of the abscess, has a different clinical course and management.[27] A lung abscess may erupt and form an adjacent empyema. Empyema is defined strictly by involvement of the pleural tissues, however.

In adults, lung abscess has been described as a disease of male alcoholics that was managed with surgery.[52,99] Lung abscess in children was recognized early on as having a different etiology and course than lung abscess in adults.[81] As is true of many infectious diseases, it continues to change as the human host and the microbial environment change. The incidence of lung abscess has declined precipitously in the modern era. Smith[135] reported lung abscesses in 0.33 percent of pediatric admissions in 1934, and Emanuel and Shulman[37] reported a rate of 0.012 percent from 1985 to 1990. In major pediatric referral centers in Chicago, Houston, Dallas, and Montreal, the incidence of lung abscesses has ranged in the last 2 decades from 1.5 to 4.7 cases per year.[5,18,40,68] Many of these cases developed in compromised hosts.

Improvements in pediatric diagnosis and care have resulted in a decrease in the number of cases related to underlying diseases. The morbidity and mortality rates also have decreased with use of antibiotic therapy and

modern critical care medicine. In 1920, Wessler and Schwarz reported a 33-percent mortality rate, with "invalidism" and hemiplegia occurring in another 27 percent.[131,150] The mortality rates in modern U.S. reports of lung abscess were 11 percent (1982 to 1993)[18] and 4 percent (1985 to 1990),[69] and 18.5 percent mortality was reported in Taiwan (1987 to 2003).[56]

Although lung abscesses occur in children of all ages, two studies have suggested that the trend is away from children younger than 5 years of age to an older population.[18,47] In other studies, the median age ranged from 7 to 9.5 years.* No consistent racial or sexual predisposition to this condition in children has been identified. In the 1950s, one series found boys to be more at risk than girls.[35] Specific risk factors for development of lung abscess in pediatric patients include predisposition to aspiration, hematogenous spread, or compromised immunity.

Pathophysiology

Two main mechanisms explain formation of a lung abscess. The first mechanism is the introduction of pathogens directly into the air spaces, which typically results in solitary abscesses. The abscess typically follows aspiration, with a resultant neutrophilic reaction and necrosis. Lung abscesses complicated tonsillectomies in one third of cases in a 1920 report.[82] The abscesses were theorized to result from aspiration during the operative procedure[67] and characteristically developed 13 to 14 days after the procedure.[82] Great improvements in modern pediatric anesthesia with careful efforts to prevent aspiration have rendered this complication uncommon today. Most lung abscesses related to aspiration are polymicrobial and include anaerobes. The prevalence of fluoride and the low incidence of dental disease in children may be additional factors for the reduced incidence of lung abscess in children, although aspiration pneumonia does occur in the absence of dental disease. Aspiration of a foreign body is a rarer trigger of abscess formation.[80]

The second mechanism in the formation of lung abscess is hematogenous spread. Hematogenous seeding of the lung can lead to an initial pneumonia that develops into an abscess with further organization and cavitation. Primary pneumonia rarely progresses to necrosis and abscess in modern times; this phenomenon is explained largely by the ready accessibility of antibiotics. Emboli from the venous circulation (i.e., septic thrombophlebitis) and right side of the heart (i.e., endocarditis) can cause single or multiple lung abscesses, which often are subpleural. Infection in the head and neck area also is a risk factor for vascular spread to the lung, with resultant lung abscess.[61] Abscesses are found more often with sensitive tools, such as CT. Modern reviews of children suggest that single abscesses are found more frequently than multiple abscesses.[8,18,69]

A lung abscess tends to have irregular margins, with occasional bullae, and can dissect into adjacent tissues, such as the mediastinum, bronchi, and pleural space. If the abscess ruptures into a bronchus, air enters and an air–fluid level can be seen radiographically. Dissection into the pleural space creates a purulent effusion, with air noted only if an anaerobic process is present. Dissection into the mediastinum causes a widening of the mediastinum. Air is detected if communication occurs with a bronchus or in the presence of anaerobes.

Microscopically, a lung abscess is definable by a collection of necrotic material (i.e., highly neutrophilic inflammation); a surrounding irregular, fibrotic wall; and microvascular infarcts. Lymphocytes often are present and seem to play a regulatory role in the formation of the abscess.[65]

The role of preceding viral infection in undermining phagocytic host defenses is supported by the observations of preceding respiratory symptoms in patients with lung abscesses that manifest primarily in cold weather[5,18] and typically after well-defined viral illnesses, such as varicella, measles, and influenza.[35,38,77] The impact of chemotherapy on phagocytes also may explain the increased numbers of lung abscesses in patients with leukemia and other cancers.

On a macroscopic scale, lung abscesses tend to develop in all parts of the lung. If associated with aspiration, the anatomic site depends on whether the patient was supine or erect at the time of aspiration. Supine patients develop abscesses in the posterior upper and lower lobes, and erect patients develop infection in the middle and basilar lower lobes. Generally, the tendency is for aspiration-related abscesses to develop more on the right side than on the left, presumably because of the vertical anatomy of the right stem bronchus.[18,34]

Physicians have grouped lung abscesses into primary and secondary categories, presuming that primary and secondary abscesses have different microbiologic factors, management approaches, and outcomes. The arbitrary nature of this distinction is apparent when appreciating how much the microbiology, clinical course, management, and outcome of both conditions overlap.[44] Primary abscesses occur in previously normal hosts without a history of trauma or aspiration of a foreign body. Secondary abscesses occur in the setting of underlying medical illnesses predisposing to infection, airway obstruction, embolization, or aspiration. In an earlier series, secondary abscesses were found more often in children younger than 1 year of age, but this difference was not corroborated in a later study.[18] Primary abscesses were found in 64 percent of patients in Chicago,[18] 33 percent in Houston,[69] 45 percent in Little Rock (1989 to 1994) (unpublished data), 30 percent in Toronto (1956 to 1965),[38] and 30 percent in Taiwan (1987 to 2003).[56]

In the modern era, lung abscess should trigger a search to exclude underlying factors that may have prognostic value and lead to treatment of the underlying disease. In children, a classic presentation would be any child with altered mental status, associated swallowing dysfunction, or both conditions. Foreign bodies can obstruct normal clearance of pathogens and precipitate the development of a lung abscess.[18,39] Obstruction predisposes to lung abscess rarely in children with metastatic disorders. Ineffective cough in patients with neurodegenerative or myopathic disorders is another risk factor

*References 5, 8, 18, 27, 56, 69.

for developing lung abscess, similar to that in an adult alcoholic. Patients with leukemia and patients who are receiving chemotherapy also are at increased risk. Occasionally, a bronchogenic cyst can become infected and mimic a lung abscess. Tricuspid or pulmonary valve endocarditis in children with complicated congenital heart disease places them at risk for developing lung abscesses.

Immunodeficiency is another risk factor for development of a lung abscess. Patients with chronic granulomatous disease and hyper-immunoglobulin (Ig)E syndrome typically are found to have lung abscesses. Patients with hypogammaglobulinemia may develop abscesses, although bronchiectasis is the more characteristic finding. The same is true for patients with immotile cilia syndromes and cystic fibrosis, although in the latter group, large abscesses are uncommon.[56] Among pediatric patients, HIV-1 infection has not been reported as a risk factor in series from Chicago and Houston.[18,69] Studies by these authors and others of 46 reported cases of secondary lung abscesses showed associations as follows: neuropsychiatric cases (16), hematologic and oncologic disorders (11), primary pulmonary disease (8), immunodeficiency (4), congenital heart disease (2), and 1 each of solvent aspiration, foreign body aspiration, prematurity, chromosomal disorder, and endocrinopathy.[53,133]

TABLE 24-5 **Symptoms and Signs in Patients with Lung Abscess**[142]

Symptom	No. Cases	Percentage
Fever	38	84
Cough	24	53
Dyspnea	17	38
Chest pain	11	24
Anorexia	9	20
Purulent sputum	8	18
Rhinorrhea	7	16
Malaise/lethargy	5	11
Hemoptysis	4	9
Diarrhea	4	9
Nausea/vomiting	3	7
Irritability	3	7
Otitis media	2	4
Seizures	2	4
Weight loss	1	2
Sore throat	1	2
Lymphadenopathy	1	2

Microbiology

The microbiology of lung abscesses is evolving as patients and antibiotics change.[52] In the preantibiotic era, streptococci and *M. tuberculosis* were the most commonly reported causes of lung abscesses. After penicillin use began and tuberculosis skin testing, treatment, and control programs became widespread, staphylococci most frequently were recovered from lung abscesses.[53] Development of better culture techniques also increased the identification of anaerobes in lung abscess material; in past eras, these organisms probably were present but not recovered. Anaerobes were suspected by the fetid odor of abscesses, the time course of postoperative aspiration infections, and Gram stains of tissue and pus, which showed fusobacteria and spirochetes.[67,81] Table 24-5 summarizes the microbiology of pediatric lung abscesses reported from 1976 to 2006.

The primary role of anaerobes in lung abscesses has been assumed in aspiration pneumonias. Anaerobes are prominent in the oral cavity and have been recovered from the abscesses of patients with dental disease.[7] Successful growth occurs when specimens are transported in a closed syringe, with culture inoculation beginning in less than 10 minutes.[8,69] In one study of developmentally delayed children with seizure disorders, poor dental care, and suspected aspiration, transtracheal polymicrobial infections with aerobes were found in 9 of 10 samples. An average of 6.2 isolates was recovered per patient. *Peptostreptococcus* and *Bacteroides* spp. were the anaerobes recovered most frequently.[8] In a larger group of 45 children, 15 of whom had primary abscesses, 14 had polymicrobial infections.[69] Older children with neurologic disorders were the primary patients with anaerobes in both studies. Anaerobes, *S. pneumoniae*, nontypeable *H. influenzae*, and *S. aureus* have been recovered from normal patients.[24,69]

The role of tissue lysins and toxins depends on the pathogen and is thought to be crucial for the development of lung abscesses. In mixed infections, synergy probably occurs among the pathogens as proposed by Smith in 1934.[67] Nosocomial pathogens are becoming frequent causes of lung abscesses because of the increased numbers of patients with extended hospitalizations and use of advanced-generation antibiotics. The widespread use of third-generation cephalosporins has resulted in resistant *Enterobacter* spp. and other gram-negative organisms being recovered in secondary lung abscesses. In the report by Tan and associates,[142] fungal abscesses occurred in 6 of 34 cases and always were associated with debilitated, chronically hospitalized patients. Immunosuppression no doubt contributes to the recovery of other unsuspected organisms (e.g., *Neisseria mucosa*, *S. pneumoniae*, and *Legionella* and *Citrobacter* spp.)[16,17,28,54,60] and underscores the value of obtaining specimens in chronically hospitalized patients, atypical cases, and patients not responding to empirical treatment.

Among otherwise normal hosts, tuberculosis can be a cause of single and multiple abscesses. In patients with an international travel history, unusual pathogens such as parasites (e.g., hydatid cysts)[19] and regional bacteria (e.g., *Pseudomonas pseudomallei*) should be considered.

Rarely is sputum useful in defining the pathogens in a lung abscess because of three factors: (1) sputum typically is contaminated with abundant mouth flora; (2) if the lung abscess is not ruptured, no direct communication of the pathogens in the abscess occurs with the airway; and (3) sputum is difficult to obtain in preadolescent children. Obtaining cough cultures, performed by gagging a young child and culturing the coughed sputum collected on a swab before it can be swallowed, frequently

is unsuccessful. A skilled clinician occasionally can acquire useful information, however.

Bronchoscopy is effective in recovering relevant organisms if the abscess has ruptured and has therapeutic value because it may assist in clearing secretions from the airway. It has been performed infrequently in pediatric practice in the past because of a lack of skilled personnel and pediatric equipment and fear of rupture of a large volume of purulent material into the airway. Rigid bronchoscopy rarely is used to drain the abscess, but, when performed, highly informative microbiologic information may be obtained. Transtracheal aspirates, likewise performed in few pediatric patients, have similar value. The upper airway frequently is colonized in debilitated patients, and microbiologic information obtained must be interpreted with care. Direct aspiration of the abscess, typically under CT or ultrasound guidance,[70] is the most common way to provide microbiologic data and plan antimicrobial therapy. Aspiration may have therapeutic value in decompressing the abscess.

Clinical Features

Most patients with lung abscesses have had symptoms for 1 to 3 weeks before being hospitalized.[18] Fever is reported to be associated with 100 percent of primary abscesses,[18,38] and 84 percent of a mixed group of primary and secondary abscesses.[69] All patients with secondary abscesses in a small series had fever.[8] Cough occurs in 53 percent to 67 percent of cases and initially may be nonproductive, becoming purulent when rupture into a bronchus occurs. With necrosis, hemoptysis can occur. Ipsilateral chest or shoulder pain also has been described in some patients, particularly older children.[18,39] Weight loss may be present if the abscess is of more than a few days' duration. Other symptoms are listed in Table 24-5.[69]

Some differences in presentation by age exist. Neonates and young infants typically are febrile, without localizing symptoms. Older children also are febrile but may have more cough or tachypnea and focal pain.

The clinical features of a lung abscess vary with the causative organisms and patient risk factors. Patients with bacterial pneumonia can present with dramatic onset of fever and overwhelming respiratory failure, such as in staphylococcal pneumonia. In these cases, the patient often has a recent history of influenza or varicella infection. Staphylococcal abscesses may not be noticed on chest radiographs until the patient already is on ventilatory support because of the time required for an abscess to organize. Similar presentations are typical of group A β-hemolytic streptococcus and *S. pneumoniae* infections. Often, a patient has received antibiotics and a temporary defervescence occurs before the hectic fevers of an abscess reemerge. In the latter situation, the respiratory symptoms may be less notable but virtually always are present.[18] This biphasic presentation was described more than 70 years ago in postoperative aspiration[67] and continues to be typical of many lung abscesses.

Subacute presentations are typical in patients with tuberculosis or fungal abscesses and usually are associated with other chronic systemic symptoms, such as anorexia, weight loss, and malaise. Cough may be prominent. Aspiration pneumonia may take an indolent or acute course, depending primarily on the organisms in the abscess, the volume of aspirated material, and the status of the host.

The physical findings in lung abscess are limited. Children usually have fever.[38,69] Tachypnea is a variable finding. Typically, auscultation is unrevealing except in cases of very large abscesses, in which loss of normal breath sounds is perceived. Adults and older children seem to have more discrete physical findings, with rales and decreased breath sounds in approximately one third of adult cases,[52] but they are uncommon findings in young children.

An abscess can rupture into the bronchus, the mediastinum, or the pleura. In most cases, these complications are substantial. In children, all organisms seem capable of causing these complications, but polymicrobial and anaerobic infections are suspected most often. Rupture into the bronchus may not be harmful if the volume of the abscess cavity does not overwhelm the host's ability to cough and clear the material. In an immunocompromised host, rupture may lead to disseminated pneumonia and further abscesses or death. Among adult patients who died of lung abscess, 22 percent were found to have died of aspiration of the abscess contents.[20]

In an otherwise healthy individual, rupture into the bronchus can be beneficial because it decompresses the abscess and allows the affected tissues to heal more rapidly. It is associated with the sudden production of foul-smelling, abundant, and sometimes bloodstained sputum. Frank hemoptysis is uncommon. Rupture into the mediastinum can be life-threatening, can be associated with chest pain and cardiac compromise, and requires surgery to drain the resulting mediastinitis. Rupture into the pleural space results in pleuritic pain, enhancement of symptoms on inspiration, and often a more toxic presentation and may require drainage.

Routine laboratory information is of limited help. The white blood cell count and erythrocyte sedimentation rate are elevated nonspecifically, and a left shift of the white blood cell differential count typically occurs.[18] Certain laboratory tests, such as the purified protein derivative tuberculosis skin test, HIV serology, or sweat chloride test, may be helpful in revealing an underlying cause. Except for the tuberculosis skin test, such studies should not be performed routinely and should be directed by a family history or other findings, such as chronic diarrhea or lymphadenopathy. Blood cultures are helpful but are positive in fewer than 10 percent of cases.[18,69]

Differential Diagnosis

The major differential diagnoses in the management of a lung abscess are anatomic. A lung abscess must be differentiated from pneumonia, necrotizing pneumonia, pneumatocele, loculated empyema, and a purulent pleural effusion with a bronchopleural fistula. CT or ultrasound may confirm an abscess by documenting central cavitation and differentiating pleural from parenchymal tissues. An abscess may be confused with a congenital cyst, pseudocyst, hydatid cyst, saccular bronchiectasis, pneumatocele, or sequestration. Chest CT allows definition of

these entities in many cases by identifying the associated structures, such as the vascular supply and pleural borders.

Apart from the anatomic and infectious causes of lung abscess, the other rare cause is cancer. Unrecognized metastatic disease from Ewing sarcoma or osteosarcomas with associated central necrosis can mimic an abscess or, by obstructing a bronchus, can promote abscess formation.

Diagnosis

The diagnosis of lung abscess usually is made by imaging the lung. In most cases, the plain radiograph is adequate to define a lung abscess (Figure 24-3), showing a thickened cavity with an air–fluid level that can be accentuated by placing the patient in the lateral decubitus or erect position. Atelectasis often occurs as an expanding abscess compressing adjacent tissues. Pleural thickening may occur if the abscess is subpleural. Hilar adenopathy occurs in subacute situations.

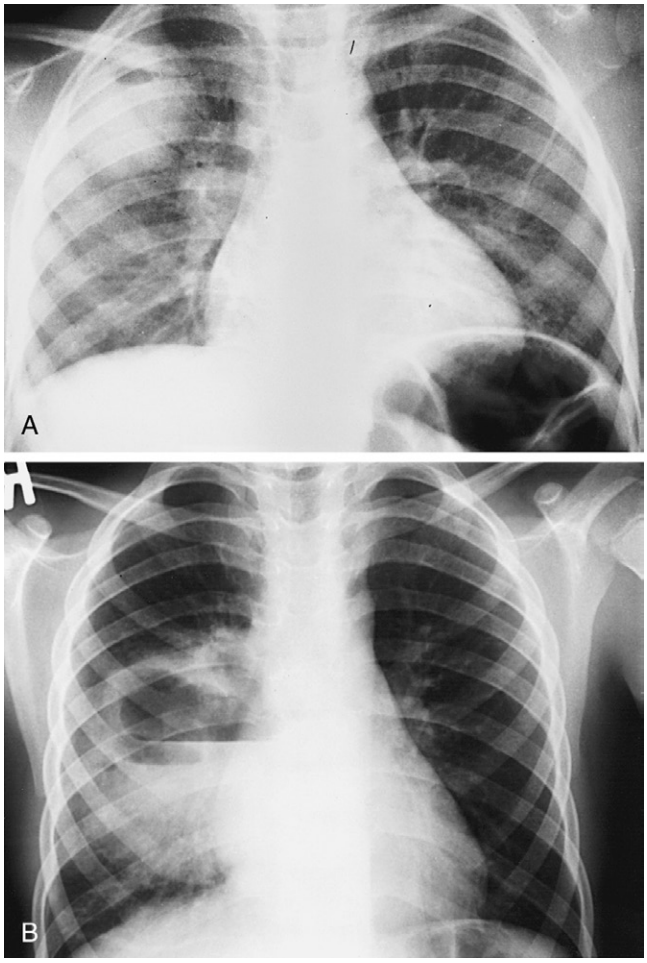

FIGURE 24-3 ■ **A,** Plain chest film of a 4-year-old boy with symptoms including cough and fever of 40° C (104° F) for 4 days. He was treated initially with oral cefaclor and re-presented with this radiograph showing an air–fluid level in the right upper lobe. On intravenous cefuroxime, he was afebrile in 48 hours and went home on oral cefuroxime axetil after 4 days. **B,** Plain chest film of a 6-year-old boy who presented after 5 days of symptoms with high fever, productive cough, dyspnea, and abdominal pain. The plain chest film reveals multiple air–fluid levels. Nafcillin and cefotaxime were begun. On day 4, an ultrasound-guided diagnostic aspiration recovered thick purulent material, but Gram stain and all cultures, including anaerobic and fungal, were negative. He was afebrile in 7 days and went home on amoxicillin-clavulanic acid at 10 days.

CT is optimal in its ability to identify smaller or multiple abscesses, document the impact of the abscess on adjacent tissues, identify cystic processes mimicking an abscess, and define an abscess for which an organized pneumonia obscures an air–fluid level on plain film.[29] CT scan of a lung abscess reveals an air–fluid level with an active rim, and the abscess is distinguished from necrotizing pneumonia, which lacks enhancement on contrast studies and lacks a distinct air–fluid level.[27] Nuclear imaging is described[13] but used rarely and adds little to the information obtained by CT.

After a presumed abscess is defined by imaging, needle aspiration of the abscess or bronchoscopic recovery of abscess fluid should allow confirmation and identification of the infectious cause of the process. Based on available pediatric studies, whether either procedure hastens recovery or reveals the microbiologic cause in pretreated individuals cannot be predicted. In a case report in which an infant had abscesses in both lungs, the time to recovery was equal in the abscess that was drained and the other abscesses that were treated medically.[41] An adult study using thin-needle aspiration showed positive cultures in 92 percent of patients not pretreated with antibiotics and in 70 percent of patients pretreated.[51]

Directly aspirating a lung abscess may be difficult or unsuccessful if the abscess is not large or peripheral, and complications such as lung laceration and sterile pleural effusions are real risks. Two groups[27,69] had satisfactory pediatric experience using direct aspiration under CT guidance (Figure 24-4). Bronchoscopy particularly is valuable if foreign bodies are suspected or pus can be recovered. When material is obtained, a putrid quality is a clue that anaerobic organisms are present. Typically, the abscess contains pure neutrophils. Occasionally, PCR or other antigen detection systems may assist in the microbiologic diagnosis when cultures are negative.[20]

Treatment

Although surgery has a role in specific situations, the treatment of small to moderate size lung abscesses in children is often successful when antibiotics alone are used.[53] In most cases, the need for surgery is limited to instances of failed antibiotic therapy or to an abscess complicated by rupture into adjacent tissues.

The initial choice of antibiotics usually is presumptive because abscess material may be unavailable. For primary lung abscesses in which no risk factors are identified and in the absence of positive blood cultures, the recommended approach is to begin therapy with a regimen that covers *S. aureus*, *S. pneumoniae*, and the anaerobic microorganisms that normally are found in the upper respiratory tract. Clindamycin, ampicillin plus sulbactam, and ticarcillin plus clavulanate frequently are used in this setting.

For patients at risk for aspiration or who are immunocompromised, gram-negative pathogens also must be

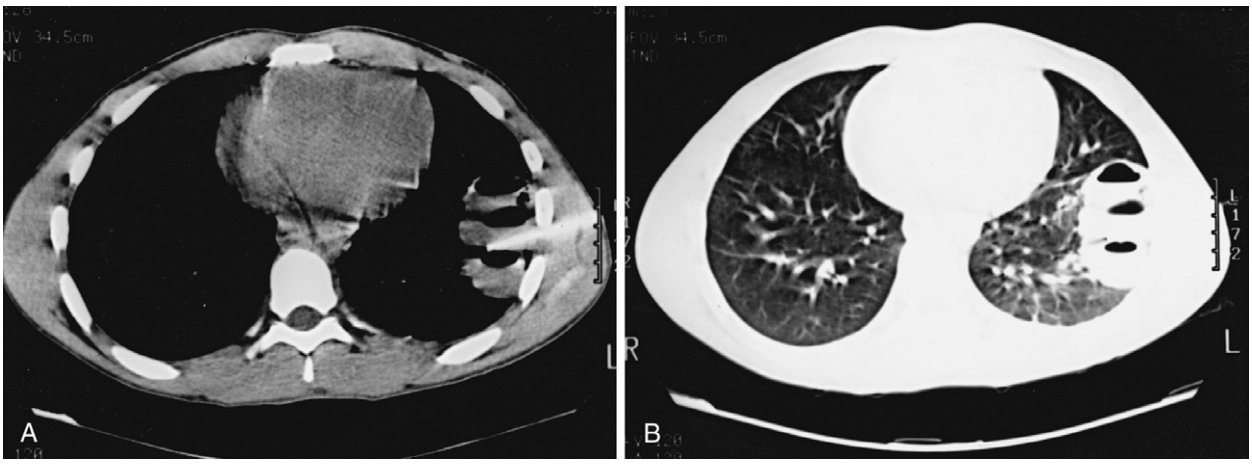

FIGURE 24-4 ■ **A** and **B,** Computed tomography (CT) scans of a 15-year-old boy who, 4 days before admission, reported a mild aspiration during fresh-water swimming. He awoke the next day with chest and back pain. He then developed low-grade fever. A plain chest film showed a large, thick-walled abscess in the left lower lobe. CT scans show insertion of a 20-gauge needle into the abscess on the first day of admission **(A)** and detail of the wall thickness and cavitation **(B)**. *Haemophilus influenzae* grew from the aspirate. Ampicillin-sulbactam was initiated and continued for 14 days.

considered. This spectrum of pathogens can be addressed with one of several drug regimens—clindamycin and cefotaxime (or an aminoglycoside); ticarcillin plus clavulanate or piperacillin plus tazobactam; or nafcillin (or cefazolin), gentamicin, and metronidazole. The possible emergence of more penicillin-resistant species, such as the milleri group of streptococci and *Klebsiella*, in community-acquired disease of adults and children supports these broad-spectrum regimens in children.[30,57] Patients with cystic fibrosis are particularly vulnerable to *Pseudomonas* spp. and should receive an aminoglycoside plus an additional antipseudomonal penicillin or cephalosporin. Carbapenem therapy would be an alternative. When endocarditis is present, treatment (e.g., vancomycin plus gentamicin with or without anaerobic coverage) should be provided for staphylococci, streptococci, and enterococci while awaiting results of blood cultures.

S. pneumoniae has been isolated infrequently in lung abscesses (Table 24-6). Most patients with isolates with reduced susceptibility are still successfully treated because achievable levels of penicillins exceed the penicillin G MICs of 0.12 to 2.0.[48] Drug resistance to *S. aureus* is a much more concerning issue in lung abscess, and empirical therapy with vancomycin is required if MRSA is suspected while waiting for confirmation, especially if the patient is critically ill.

If culture information is available, therapy is directed specifically at the pathogens isolated. In most patients, oral or intravenous antibiotic therapy has been administered before culture results are available and may affect which organisms are recovered.[16,17] For this reason, coverage should be extended to include organisms that are likely to be present but are not recovered, such as anaerobes, in a setting of aspiration.

All bacterial lung abscesses should be treated with intravenous therapy until the patient is stable and no longer toxic. In approximately two thirds to four fifths of

Data from references 4, 16, 23, 32, 37, 63, 72, 78, 85, 92, 93, 104, 106, 134, 141, 144, 148.

These data were reported in the literature from 1976 to 2006. The isolates were recovered by direct aspiration of abscess contents, bronchoscopic aspiration, transtracheal aspiration, blood culture, or culture of surgical specimens. Data from case reports focused on procedures are included, whereas data from case reports focused on the organism recovered are not.

patients, this condition occurs within 3 to 7 days of instituting intravenous therapy.[18,40] After the patient has been afebrile for 48 to 72 hours, initiation of oral therapy may be considered. Certain oral drugs, such as amoxicillin plus clavulanate and clindamycin, can achieve therapeutic serum levels and are effective against the spectrum of organisms in lung abscesses.

The length of total therapy for a lung abscess should be 2 to 3 weeks. Complicated infections should be treated intravenously until fever has disappeared and no evidence of continuing inflammation exists. An additional 2 to 3 weeks of oral treatment should follow. Radiographic resolution of a lung abscess that is not drained occurs over the course of weeks. Even with drainage, resolution may not occur more rapidly. Chest radiography should be repeated every 1 to 2 weeks until complete resolution is documented.

Tuberculous lung abscesses may rupture spontaneously into the pleura. Treatment is not directed at the immediate abscess or pleuritis but at preventing spread if it erupts into a bronchus. Preventing reactivation several years later is another goal of therapy.

Clinical failure is defined by persistent fever and toxicity. The length of time treatment with intravenous antibiotics should continue before declaring therapy a failure is not clearly defined. Suggestions in the literature range from 1 to 3 weeks.[2,5,53] When clinical failure occurs, several options are available, including drainage of the abscess, which permits identification of the organisms causing the disease process.

Needle aspiration (one or more) also is possible under fluoroscopy, ultrasonography, or CT guidance.[27,35,36] Simple CT-guided needle aspiration leads to relief of symptoms in approximately two thirds of cases within 48 hours.[27] The risk for complications seems to be low.[27,36] Percutaneous transthoracic tube drainage has been used in pediatric lung abscesses.[14,39,50,71,76] The risk is lowest if the abscess is peripheral, and adhesion of the opposing pleural surfaces is a consequence of the inflammatory process. When this adhesion occurs, the needle or catheter does not traverse the pleural space. Catheter drainage may be attempted in abscesses larger than 4 cm in diameter,[2,27] using 8- to 10-French pigtail catheters. Smaller abscesses are technically difficult to manage.

Chest tube thoracostomy previously was the standard therapy of lung abscesses[43,45]; it is now recommended only when conservative therapy fails and may play a role in patients with large abscesses if the abscess abuts the parietal pleura and provides a direct path from the exterior surface to the abscess.[42] A 25-year review of the literature found that significant complications, such as hemothorax, pneumothorax, bronchopleural fistula, empyema, and catheter occlusion, occurred in 9.7 percent of cases, with an overall mortality rate of 4.8 percent.[71]

Surgery for lung abscess is not well described in the pediatric literature. One report that combines surgery for lung abscess and necrotizing pneumonia had no mortality in the postsurgery period and a reversible complication rate of 10 percent.[68] Indications for surgery included associated pyopneumothorax, size of the abscess, and tension pneumatocele. Another possible surgical indication is proximity of a lung abscess to the mediastinum. In the face of antibiotic failure, an open lung procedure and wedge resection may be required, depending on the location of the abscess.[6] The procedure typically is successful and often obviates the need to perform a lobectomy.[31] In a complicated case, such as with a gangrenous lung, lobar resection may be necessary. Managing an infant with a lung abscess has required surgery more often than in older children.[66,77]

Prognosis

The outcome for pediatric patients usually is good when lung abscesses are uncomplicated, and recovery is more rapid than in adults.[44] Most patients have complete symptomatic and radiographic resolution in 3 to 6 weeks, with normal pulmonary function tests at follow-up.[5,18] Complicated disease associated with thoracostomy tubes and empyema more likely leads to residual symptoms (e.g., pleurisy) and persistent effusions or pleural thickening on radiographs. In reports published since 1982, half of patients with lung abscess have required surgical intervention, such as thoracentesis to drain an empyema, lobectomy, or decortication, and 20 percent have required lobectomy or decortication.[5,8,18,69] Lung abscess associated with underlying disorders has a higher mortality rate.[26] If patients require lung resection, they may experience immediate surgical complications; long-term exercise tolerance may be limited, and other problems, such as scoliosis, may develop. One study found normal pulmonary functions in patients studied after undergoing lobectomy, however.[47]

Rarely, a residual cavity may develop and become superinfected. The mortality rate is 4 to 11 percent for patients with primary and secondary lung abscesses.[18,69] Higher risk for morbidity and mortality occurs in patients with secondary abscesses who have complications caused by either a decrease in host resistance or underlying disease.[18,52,68,69]

Additional Complications

Necrotizing pneumonia is a complication of lung infection. In contrast to simple pneumonia more destruction of tissue occurs with limited purulence caused either by toxins of the pathogen or by infarction of tissue. The necrotizing process can be limited, requiring no special intervention or extensive surgery and having a more prolonged clinical course. The necrotizing process can lead to fistulas, pneumothorax, and pneumatocele.[58] Sawicki and colleagues[125] have reported an increased incidence of necrotizing pneumonia in children in the new millennium with an increased frequency of *S. aureus*. This has been noted in children of all ages, including infants.[131] However, necrotizing pneumonia is also described for diverse organisms, including *S. pneumoniae* (particularly nonvaccine strains), group A streptococcus, *Clostridium perfringens*, *M. pneumoniae*, and adenovirus.

The formation of a bronchopleural fistula can occur as a complication of the underlying pneumonia or as

a complication of treatment with a chest tube or postoperatively from débridement. Rates of 55 percent to 67 percent for fistula formation have been reported associated with necrotizing pneumonia.[49,86] An increased risk was noted in the United Kingdom in 2008 to 2009 (1%) in contrast to 2002 to 2007 (33%).[6,94] Thin-section CT may be required for a radiologic diagnosis.[151]

Pneumatoceles form as a result of tissue necrosis. The development occurs as an acute or delayed part of the pathologic process, with resolution occurring in some cases depending on the size of the defect. A Brazilian study reported pneumatoceles in 8.3 percent of 394 pediatric pneumonia cases and a spontaneous resolution rate of 85 percent.[74] *S. aureus* is most typically identified with this complication, although a pneumatocele represents a potential common pathway for pathologic resolution of a pneumonia and has been reported in pneumonia caused by multiple pathogens. Ramphul and colleagues[114] reported a 20 percent incidence of cavitary disease in patients with empyema, mostly associated with *S. pneumoniae*.

Pneumothorax is an uncommon complication of pneumonia but can occur in any setting in which lung damage creates a ball-valve effect trapping air in the pleural space. Necrotizing pneumonia is one predisposing factor. *P. jiroveci* in HIV disease has been reported as a specific cause of pneumothorax.[109] Other complications occur rarely secondary to pneumonia. Many of these represent local extension of an infected lung or pleural tissue into adjacent tissues including the airway, blood vessels (hemoptysis), bone, and nervous tissues (recurrent laryngeal nerve–Horner's syndrome with apical pneumonia). Pericardial effusions are surprisingly common in patients with parapneumonic effusions. Roberts and associates reported a rate of 54.2 percent although a single patient in their series of 48 had hemodynamic compromise.[116] Other complications result from the hematogenous spread of pathogens causing the pneumonia including sepsis, meningitis, osteomyelitis, other solid organ abscesses, and endocarditis. Finally, complications can arise from the immune response to pneumonia.

CHAPTER 25

Cystic Fibrosis

Peter W. Hiatt • Ruth Ann Luna • Kathryn S. Moffett

Cystic fibrosis (CF) is the most common inherited lethal disease of whites. It occurs primarily among individuals of Central and Western European origin and affects more than 30,000 Americans and 60,000 people worldwide.[439] The estimated incidence in the United States is 1:2000 to 1:2600 white,[452] 1:19,000 black, 1:11,500 Hispanic, and 1:25,000 Asian-American live births.[270] CF has an autosomal recessive mode of inheritance. Affected individuals are phenotypic homozygotes, and both parents usually are heterozygotes or carriers. The carrier frequency in whites in the United States is approximately 1/25, with full siblings of children with CF having a one in four chance of being affected.

Mutations in a single gene located on the long arm of chromosome 7 account for the defective protein in CF.[439] A range of different mutations at the DNA level account for the abnormal protein. The most common mutation, p.Phe508del, is the absence of three sequential nucleotides, which leads to the deletion of phenylalanine at the 508 position on the CF transmembrane conductance regulator protein (CFTR). Approximately 70 percent of individuals with CF have this mutation, and half of CF patients are homozygous for p.Phe508del. To date, more than 1800 mutations in the *CFTR* gene have been identified,[84,85] but fewer than 25 occur with a frequency of more than 0.1 percent.[147] Certain populations have higher frequencies of specific mutations, such as W128X in Ashkenazi Jews[270] or G551D in French Canadians.[339]

Five classes of mutations have been proposed to account for reduced CFTR chloride channel function.[166,339,438,467] Class 1 mutations are mutations in which stop codons or frame shift mutations cause early termination of mRNA translation and minimal to no protein production. In class 2 mutations (p.Phe508del), protein fails to mature, resulting in little expression of CFTR at the cell membrane. Class 3 and class 4 mutations are associated with defective regulation and decreased conductance of chloride at the cell membrane. Protein production and transit to the cell surface occur, but altered chloride conductance is present or chloride conductance is nonexistent. Class 5 mutations are splice site mutations, which affect the amount of CFTR produced.

Disease expression in CF is affected by CFTR mutations, genetic modifiers, and the environment.[263] The presence of more than 1800 mutations for CFTR has prompted investigators to evaluate the association of genotype with clinical disease. The Cystic Fibrosis Phenotype Genotype Consortium has shown that certain mutations from classes 3 to 5 are associated with pancreatic sufficiency and lower sweat chloride levels in contrast to pancreatic insufficiency[90,446]; however, minimal correlation of CF genotype with the severity of pulmonary disease has been observed. Measurement of lung function is highly variable in patients with the same CFTR mutation (e.g., p.Phe508del), suggesting other genetic and nongenetic factors determine the severity of lung disease. In a study of monozygotic and dizygotic twins, equal contribution of genetic and nongenetic factors contributed to the variance observed in pulmonary function; that is, approximately 50 to 60 percent of the variance observed in lung function was secondary to genetic factors.[72,445] Several modifier genes have been identified that affect disease severity of different organ systems in CF.[71,93,108,205,385] The wide variation in pulmonary disease observed in CF reflect the effects of environment, patient compliance, polymorphisms in CFTR, and modifier genes that affect the function of CFTR.

CFTR is a glycoprotein expressed at low levels by surface epithelial cells in the lung, sweat glands, pancreas, liver, large intestine, and testes.[327] Higher levels of expression have been reported in submucosal glands. CFTR protein is a member of a group of membrane transport proteins known as the *ABC-transporter superfamily*.[185] Researchers have confirmed that CFTR functions as an apical chloride channel mediated by cyclic adenosine monophosphate containing 1480 amino acids. It is composed of two membrane-spanning domains, two nucleotide-binding domains that interact with adenosine triphosphate, and a regulatory domain.[6] Activation of the channel is regulated by protein kinase A, which serves as a target for phosphorylation. CFTR in epithelial cell membranes may influence the expression of other proteins important in regulating inflammation, ion transport, and cell signaling, altering the CF phenotype.[338] CFTR regulates the activity of separate calcium-activated chloride channels and downregulates sodium transport, balancing the rates of chloride secretion and sodium absorption.[139,204,217]

CFTR is responsible for the proper hydration of secretions in the airway, pancreas, and other tissues. An inability to secrete chloride and excessive absorption of sodium and water contribute to altered luminal secretions in patients with CF. In the lung, this alteration leads to decreased airway surface liquid, decreased mucociliary clearance, and a predisposition to chronic bacterial infections.

Clinical Manifestations

Individuals with CF have exocrine gland dysfunction, which results in progressive suppurative obstructive lung

TABLE 25-1 Clinical Features of Cystic Fibrosis at Diagnosis

0-2 Years
Meconium ileus
Obstructive jaundice
Hypoproteinemia and anemia
Bleeding diathesis
Heat prostration and hyponatremia
Failure to thrive
Steatorrhea
Rectal prolapse
Bronchitis/bronchiolitis
Staphylococcal pneumonia
2-12 Years
Malabsorption
Recurrent pneumonia and bronchitis
Nasal polyps
Intussusception
>13 Years
Chronic pulmonary disease
Clubbing
Abnormal glucose tolerance
Diabetes mellitus
Chronic intestinal obstruction
Recurrent pancreatitis
Focal biliary cirrhosis
Portal hypertension
Gallstones
Aspermia

From Maclusky I, Levison H. *Kendig's disorders of the respiratory tract in children.* 5th ed. Philadelphia: W. B. Saunders; 1990, p. 701.

disease, pancreatic insufficiency (85% to 90%), elevated sweat electrolytes, male infertility (>95 percent), and female infertility. Less common manifestations include hepatobiliary disease, osteoarthropathy, diabetes mellitus, nasal polyposis, and meconium ileus (Table 25-1).[63,86,87]

The potential relationship between genotype (the genetic constitution of an individual) and phenotype (the physical expression of that genotype) in CF is an area of active clinical investigation. To date, the correlation of genotype to phenotype has not led to many clear associations between severity or course of pulmonary disease and type of genetic mutations.[50,202] A family-based study of CF involving monozygotic twins, dizygotic twins, and siblings reported that a significant portion of the variability in pulmonary function was attributable to heritability, independent of CFTR genotype.[424] This finding suggests that modifier genes account for a significant amount of the variance observed in CF lung disease. Numerous candidate modifier genes have been investigated to account for the variance in CF pulmonary disease, with more recent reports identifying transforming growth factor-β1, mannose binding lectin, interferon (IFN)-related developmental regulator 1 gene, and interleukin (IL)-8 gene as candidates.[109,251] These gene modifiers affect response to infection and inflammation.[173,424] In addition to modifier genes, environmental factors, including passive smoke exposure, infection, and socioeconomic status, have been associated with reduced lung function.[77,200,280,340,355] Multiple mutations, incomplete understanding of the physiologic function of CFTR, and the role of modifier genes have delayed understanding of the genotypic influence on phenotype in CF lung disease.

A strong association between pancreatic function and genotype has been reported for individuals homozygous for p.Phe508del.[31] Most patients homozygous for p.Phe508del have pancreatic insufficiency.[83] Obstruction of the pancreatic duct begins in utero, resulting in fibrosis and loss of exocrine pancreatic function. Pancreatic fluid from patients with CF is low in enzyme and bicarbonate concentrations, resulting in maldigestion of fat and protein. Clinically, children commonly present with steatorrhea, protein-calorie malnutrition, muscle wasting, and progressive failure to thrive. A voracious appetite is characteristic, and stools are described as bulky, greasy, and foul-smelling. Approximately 10 to 15 percent of patients have enough preservation of pancreatic function to allow for normal digestion of food (pancreatic-sufficient).[101] At least five mutations from classes 3 to 5 described earlier are associated with pancreatic sufficiency, whereas almost all patients homozygous for p.Phe508del have pancreatic insufficiency.[83]

Failure to thrive is a common complication observed at the time of diagnosis; however, with the implementation of newborn screening, this complication is less common. If malnutrition is severe, hypoproteinemia and edema are observed. In addition, malabsorption can lead to vitamin deficiency, especially of fat-soluble vitamins A, D, E, and K. These problems can be reversed with pancreatic enzyme replacement therapy, oral nutritional supplements, and routine vitamin supplements. Infants diagnosed by newborn screening may not have overt malabsorption for several months after birth even with a severe mutation such as p.Phe508del. However, with time, pancreatic function is lost and symptoms of malabsorption develop.

Glucose metabolism often becomes impaired with age, because fibrosis of the pancreas occurs in patients with exocrine pancreatic insufficiency. In the 2010 CF registry, 31 percent of adults were reported to have impaired glucose tolerance or CF-related diabetes with and without fasting hyperglycemia. Decreased secretion of insulin and reductions in peripheral glucose use and hepatic insulin sensitivity are observed in patients with impaired glucose tolerance.[260] CF-related diabetes has features of type 1 and 2 diabetes. The prevalence increases with age and is associated with increased morbidity and mortality disproportionately in women.[256,259] Progressive fibrosis of the pancreas causes destruction of insulin-producing β cells within the islets of Langerhans. In addition destruction of islet α cells impairs glucagon secretion therefore ketoacidosis is rare. Microvascular complications have been reported in up to 20 percent of patients with CF-related diabetes.[8] Diabetes in CF is common and strongly determined by genetic modifiers.[27]

Liver disease in CF is associated with pancreatic insufficiency.[297] Approximately 25 percent of patients with CF develop focal biliary cirrhosis, but fewer than 5 percent progress to multilobar biliary cirrhosis and portal hypertension. In the absence of CFTR, bile becomes inspissated and associated with periductal inflammation and

fibrosis. Liver function tests frequently are abnormal, as is a small, poorly functioning gallbladder. Cholelithiasis has been reported in 12 percent of patients and may be related to loss of bile acids in the stool.[75,127,130] Meconium ileus, the thick inspissated meconium that mechanically obstructs the distal ileum, occurs in 8 to 20 percent of newborns with CF. It also is associated with pancreatic insufficiency.[201] Both CFTR and modifier genes are thought to play an important role in the development of meconium ileus.[26,56] A similar syndrome (distal intestinal obstructive syndrome) mimicking meconium ileus can occur in older children and young adults with CF. Complete or incomplete obstruction can occur in the terminal ileum or proximal colon. Higher rates are observed in patients with pancreatic insufficiency, positive history of meconium ileus, and previous episodes of distal intestinal syndrome.[74]

Absence of the vas deferens with secondary aspermia renders 98 percent of men with CF infertile.[103] Sexual potency is normal, and with microsurgical techniques for sperm aspiration, affected men can become biologic fathers.[247] Men with congenital absence of the vas deferens can have abnormal CF alleles with little clinical expression of disease other than the reproductive system. Fertility in women with CF may be decreased secondary to amenorrhea (malnutrition) and dehydrated cervical mucus.[391] Pregnancy in women with mild-to-moderate disease appears to be well tolerated and not associated with an increased risk for death.[112,150,158] The live birth rate is 1.9/100.[88]

Pulmonary disease is the primary cause of morbidity and mortality in patients with CF.[451] Expression of CFTR has been localized to the airways and submucosal glands of the lung.[410] Clinical studies in young children with CF have found significant inflammatory changes in the airways in bacterial-positive and bacterial-negative patients.* Imaging studies using high-resolution computed tomography (CT) in infants with CF describe the presence of thickened airway walls and nonhomogeneous air trapping.[94,232,242] The lungs are morphologically normal at birth; within weeks, they begin showing evidence of small airway abnormalities and inflammation. Small and medium-sized airways become obstructed, and neutrophils are the inflammatory cells primarily recovered from bronchoalveolar lavage (BAL) fluid. An intense neutrophilic response leads to the release of proteases that cause chronic injury to the respiratory epithelium and supporting airway structure. The massive numbers of neutrophils subsequently release elastase, which overwhelms the antiproteases in the airway, contributing to enhanced destruction of tissue. Large amounts of neutrophil-derived DNA and cytosol proteins are released into the airway lumen, increasing sputum viscosity and worsening airway obstruction.[91]

Progressive bronchiectasis develops with time, leading to advanced destruction of the airways and parenchyma (Figs. 25-1 and 25-2).[128] Bronchiectatic cysts are prominent, especially in the upper lobes. Death eventually occurs from respiratory failure. Progressive deterioration of pulmonary function occurs despite the routine use of anti-inflammatory therapy, mucolytics, airway clearance, and antimicrobial agents. Progressive destruction of the airway and increasing obstruction lead to air trapping, hyperinflation, hemoptysis, and spontaneous pneumothorax.

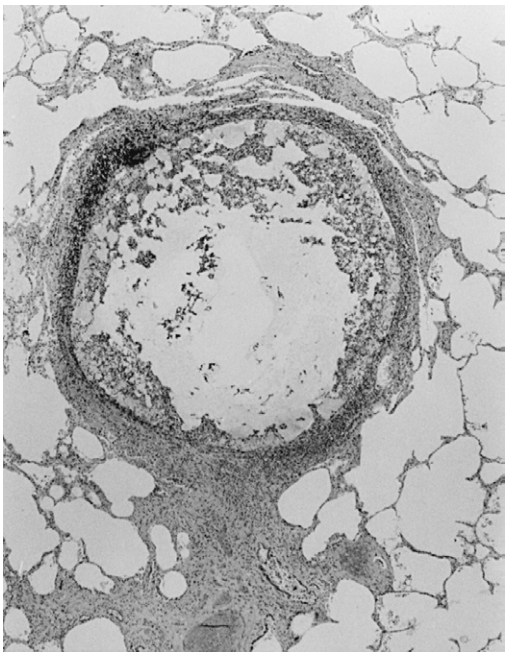

FIGURE 25-1 ■ Early stages of lung disease in cystic fibrosis are shown in this lung specimen. Airway inflammation and bronchiectasis are present. The surrounding lung parenchyma is normal.

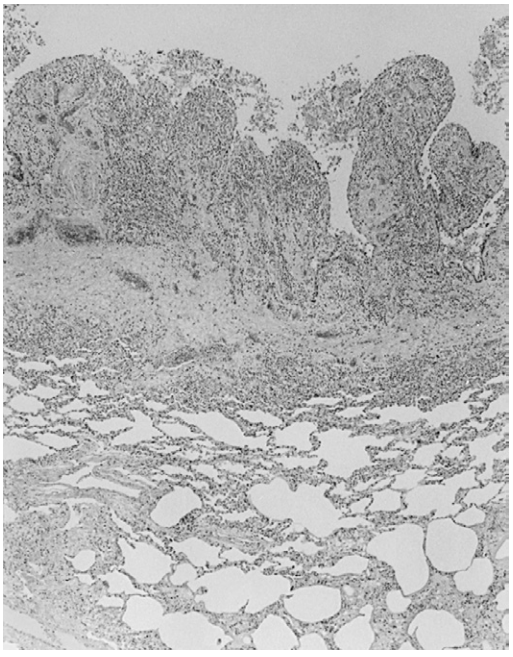

FIGURE 25-2 ■ Late stages of pulmonary disease. Epithelial ulceration of the airway, loss of smooth muscle from the airway wall, inflammation, and bronchiectasis are present in the large airway at the *top* of the photomicrograph. Compression of the surrounding lung parenchyma occurs as bronchiectasis increases.

*References 14, 91, 165, 254, 334, 335.

Many children with CF present during infancy with recurrent wheezing or persistent bronchiolitis. Most infants are asymptomatic at birth; however, many develop tachypnea, wheezing, hypoxia, and hyperinflation after having a respiratory viral infection.[171] These findings often resolve with therapy. As mucopurulent secretions increase, chronic cough develops.[63] Digital clubbing occurs gradually and correlates with severity of lung disease. Cough is the earliest symptom in infants and precedes persistent sputum production, crackles, or clubbing. It is present in half the infants in a prospective study of CF infants diagnosed by newborn screening.[127,248] Predictive risk factors included the presence of pancreatic insufficiency, infection with *Pseudomonas aeruginosa*, socioeconomic status, and ethnicity.[248] On examination, evidence of crackles and decreased breath sounds secondary to mucopurulent secretions is seen. Acute exacerbations may develop, requiring intravenous antibiotic therapy and frequent hospitalization. Approximately a third of patients with CF in the 2005 U.S. CF registry[87] experienced a pulmonary exacerbation requiring intravenous antibiotics. As lung disease progresses, tolerance for exercise is reduced, dyspnea increases, and respiratory failure develops. Marked heterogeneity occurs in the rate of progression of pulmonary disease. Some patients live to the sixth decade of life, whereas others die as a result of respiratory failure before their 10th birthday.

In 2010, the median predicted survival for individuals with CF was 38.3 years. Survival for children born in 2005 is expected to increase, with the median age approaching the fifth decade of life. In the United States, 48 percent of people with CF are 18 years old or older,[88] and within 5 years, half are expected to be older than 18 years. As life expectancy has increased, CF has become a disease of children and adults.

DIAGNOSIS

The diagnosis of CF has changed over the past 10 years. Newborn screening for CF has been adopted by the United States, Europe, Australia, New Zealand, and many Latin American countries. The CF newborn screen program identifies patients at risk for the disease by measuring values of immunoreactive trypsinogen in dried blood spots, Trypsinogen is produced in the pancreas and is released into the serum secondary to pancreatic duct dysfunction. After an abnormal immunoreactive trypsinogen value is identified, many programs perform DNA testing to identify known CFTR mutations. Other programs repeat the immunoreactive trypsinogen testing 2 weeks after the initial test. Both programs report 90 to 95 percent sensitivity and identify infants with varying disease severity.[126,432] After a positive screen, infants are referred for diagnostic testing (sweat test or molecular genetic testing). For most patients the sweat test remains the best diagnostic test to establish the diagnosis of CF. If the sweat test results are in the intermediate range, then DNA analysis may help in the diagnosis. The clinical significance of all 1800 CF mutations is unknown. Many are sequence variants without known clinical disease. Others are known to cause loss of CFTR function and associated with clinical abnormalities in one or more organ systems. Sequence analysis of the exons, introns, and promoter regions and detection of deletions and duplications identifies 98 percent of CFTR mutations.[388] Infants are generally asymptomatic at the time of diagnosis, although some may be underweight. Data from the 2010 U.S. CF registry reported that newborn screening accounted for more than 50 percent of newly diagnosed patients.[87] In the absence of newborn screening, an in utero diagnosis, or a family history of CF, a strong clinical suspicion is required for early recognition. Most children present with a history of recurrent lower respiratory tract disease and symptoms secondary to malabsorption. Approximately 15 to 20 percent of children have meconium ileus at birth, a family history of CF, or both. A consensus panel convened by the U.S. Cystic Fibrosis panel recommended a combination of phenotypic features, family history of CF, or positive newborn screen and one or more laboratory tests to diagnose CF.[129,337] Laboratory tests include identification of known CF mutations, abnormal bioelectric transepithelial membrane properties, and elevated concentrations of sweat chloride. The World Health Organization adopted similar recommendations.[453]

The quantitative pilocarpine iontophoresis sweat test is the primary test to establish a diagnosis of CF.[337] A sweat chloride concentration greater than 60 mEq/L is consistent with a diagnosis of CF. Values between 40 and 60 mEq/L are considered borderline, and values less than 40 mEq/L are normal. Infants with a positive newborn screen and sweat chloride values between 30 and 59 mEq/L under 6 months of age are considered to have values in the intermediate range, Molecular genetic testing should be pursued in these infants with indeterminate sweat chloride values. In the presence of two CF-causing mutations, a diagnosis of CF can be made. Infants with intermediate sweat test values and 1 CF-causing mutation cannot be diagnosed definitively with CF and will need to be followed longitudinally. If the sweat test is positive, it should be repeated on two separate occasions. Identification of two CF mutations by genotype is highly specific but less sensitive. Mutational analysis can be done by several different techniques, with commercial laboratories testing for the most common 30 to 87 mutations. These laboratories identify approximately 90 percent of CF mutations but leave more than 1000 mutations unidentified. Extensive screening for the remaining 10 percent of mutations is expensive. For rare mutations, gene sequencing is available.[336,337] The p.Phe508del mutation is found in 89 percent of patients with CF in the United States and a similar number of CF patients in the United Kingdom. Because each patient has two chromosomes, however, only 50 percent of patients are homozygous for p.Phe508del.

Nasal potential difference measurements assess the transepithelial electric potential difference that exists across nasal epithelium. Different patterns of potential difference are found in patients with CF.[161] Abnormalities in chloride transport and sodium absorption alters the transepithelial electric potential difference in CF in contrast to normal epithelia. The test can be useful in individuals with mild or atypical phenotypic features of CF,

TABLE 25-2 **Diagnosis of Cystic Fibrosis**

but it is not readily available and it requires experienced personnel to perform.[336,337]

Newborn screening programs are associated with long-term benefits in children with CF diagnosed shortly after birth. Improved nutritional status as a result of newborn screening has been reported in a controlled, randomized trial in Wisconsin,[126] as well as in countries other than the United States.[351] Ninety percent of screened infants in the Wisconsin study diagnosed with CF at birth maintained their weight greater than the 10th percentile in contrast to only 60 percent of unscreened controls. Children in the screened group were less likely to fall below the 10th percentile for weight and height from early childhood through 16 years of age.[49,126] In addition, cognitive function improved significantly in the screened group.[212,213] No long-term improvements in pulmonary status were observed in the Wisconsin study; however, several observational studies have reported improved pulmonary outcomes, less colonization with *P. aeruginosa*, decreased hospitalization for complications, and improved nutrition in children diagnosed by newborn screening.*

In addition to improving nutritional outcomes, newborn screening may result in improved survival rates for children. A systematic literature review of mortality in children with CF reported a survival benefit for patients diagnosed by newborn screening.[77,163] A survival effect also was shown in a study from Wales.[106] Without screening, approximately 60 percent of patients are diagnosed by the time they reach 1 year of age and almost 90 percent by the time they are 5 years. Early diagnosis through neonatal screening seems to improve nutritional outcome, with increasing evidence that these programs are associated with improved pulmonary outcomes and improved long-term survival.

The diagnosis of CF should be based on the presence of one or more clinical features (Table 25-2), a positive newborn screening test, and laboratory evidence of abnormal CFTR function. Laboratory tests include elevated sweat chloride concentration, two identifiable CF mutations, or abnormal in vivo nasal potential difference measurements made across the nasal epithelium.

PATHOGENESIS

The CFTR protein resides in the plasma membrane of epithelial cells and has several functions. In the sweat duct, it acts to absorb chloride; in the lung, it secretes chloride; and in the pancreas, it secretes chloride in exchange for bicarbonate.[403] Organs that are affected by the disease have abnormal chloride and fluid secretion, which impairs fluid movement and leads to ductular obstruction and organ damage. Five classes of CF mutations result in different amounts of CFTR expression and have been observed to produce varying clinical disease. The most common mutation, p.Phe508del, is a class 2 mutation. The CF protein is misfolded and degraded before reaching the cell membrane.[61,326]

Other classes of mutations produce CFTR that cannot be activated, is decreased in abundance, or has altered conductance. Patients with at least one "mild" allele have some low level of CFTR expression. They retain some degree of pancreatic function, have less severe lung disease, and have sweat chloride concentrations that are borderline normal.[77,94,446] Male patients with congenital bilateral absence of the vas deferens are pancreatic sufficient, exhibit little or no lung disease, can have normal sweat chloride concentrations, and are thought to have CFTR expression that is 10 percent of normal.[10] Carriers for CFTR who are heterozygotes expressing half the expected amount of CFTR are at increased risk for developing pancreatitis, allergic bronchopulmonary aspergillosis (ABPA), and sinusitis.[60,70,111,311]

The range of severity of disease is related to the production of functioning CFTR. The amount of expression of CFTR is important in the pathogenesis of CF. Variation in the severity of disease in individuals with the same genotype indicates other factors, including the environment, genetic modifiers, and medical therapy, are important in long-term outcomes, however.

The exact mechanism by which altered salt and water transport leads to abnormal secretions in the respiratory tract, pancreas, gastrointestinal tract, sweat glands, and other exocrine glands remains under intense investigation. The isotonic, low-volume model has been proposed to account for the pathogenesis of CF.[35,37] In the lung, abnormal respiratory tract secretions leading to decreased airway surface liquid seem to decrease mucociliary clearance and impair defenses to inhaled particulate matter and various microbial pathogens. The airway surface liquid is crucial for lung defense and is composed of a gel and sol layer. The gel or mucous layer is composed of high-molecular-weight mucins with carbohydrate side chains that bind inhaled particulate matter and pathogens. The sol or periciliary liquid layer consists of low-viscosity fluid to hydrate mucins and allows ciliary movement to occur. The periciliary liquid layer is 7 μm in height, allowing cilia to beat freely.

Airway surface liquid volume is regulated by the respiratory epithelium through ion transport processes. Salt concentrations can be changed to regulate the hydration of the airway lining fluid to maintain optimal mucociliary function. The absence of CFTR in the apical cellular membrane decreases the ability of cells to secrete

chloride into the periciliary fluid. CFTR inhibits the epithelial sodium channel; in its absence, excessive absorption of sodium occurs. Other channels are available for secretion of chloride (i.e., calcium-activated chloride channel) in the respiratory epithelium; however, they cannot compensate for the loss of CFTR. Chloride also can enter the cell through a chloride transporter. The net effect is increased absorption of sodium, chloride, and water, which reduces the periciliary volume, alters the composition of mucins, and decreases mucociliary clearance. The reduction in the periciliary fluid impairs ciliary movement, decreases mucus transport, markedly alters clearance, and sets the stage for airway obstruction, infection, inflammation, and progressive lung destruction.

Altered chloride channel function and fluid secretion help to explain the presence of disease in the sweat gland, intestine, pancreas, and male genital tract. The epithelial cells affected by CFTR mutations in various organs represent different channel and regulatory activities of CFTR but result in deficient secretion of fluids. This deficiency causes accumulation of mucus, obstruction, and various degrees of organ damage. Plugging of pancreatic ducts leads to chronic fibrosis, pancreatic atrophy, and loss of digestive enzymes and islet cells. Similar obstruction in the biliary tract can cause inflammation and focal biliary cirrhosis. Glandular obstruction of the vas deferens causes involution of the Wolffian duct and infertility in more than 95 percent of men with CF. Women with CF produce abnormally tenacious cervical mucus, with reported rates of infertility of 20 percent.

Dehydration of airway surfaces and defective mucociliary transport has been termed the *low-volume model*.[37] Obstruction of small terminal airways and submucosal glands with thickened mucopurulent secretions are the first signs of early disease in infants with CF. Ductular dilation, neutrophil infiltration, glandular hyperplasia, and peribronchiolar inflammation are classic findings of the disease. Mucus adherent to airway surfaces serves as a site for chronic infection. Human cell culture models of normal and CF epithelia have shown the airway surface liquid is decreased in CF,[244,404] and regulation of airway surface liquid volume depends on the regulation of sodium absorption and chloride secretion. Transgenic mouse models overexpressing epithelial sodium channels to mimic CF produce airway obstruction with mucus, neutrophilic inflammation, bacterial infection, and goblet cell hyperplasia.[238]

These findings are similar to observations in humans. Mucociliary clearance is decreased in CF.[35,206,328] Submucosal glands have high expression of CFTR.[121,164] Loss of CFTR function alters the composition of mucins produced by the submucosal glands,[190,206,429] leading to ductular dilation with mucus and obstruction. Mucus is tightly adhered to the respiratory epithelium and increases airway obstruction. Failure to clear mucous plugs, continued mucin secretion, and adherent mucus to the airway surface provides the focus for infection.

The respiratory airways of patients with CF are infected with several bacterial and viral pathogens that occur in an age-dependent order. Chronic infection with *P. aeruginosa* develops in 80 percent of affected individuals by the time they reach 25 years of age.[335] *Pseudomonas* infection is associated with a more rapid decline in lung function and increased rates of mortality[120,137] and becomes the dominant organism colonizing the CF airway. The prevalence of *Pseudomonas* infection may be decreasing.[228,320] Initial isolates from CF infants and toddlers are unique and suggest an environmental acquisition.[283,381,382] Over time one strain dominates and changes to a mucoid phenotype.[160] Evidence of person-to-person transmission from chronically colonized CF patients to younger CF children, siblings, and individuals in close contact has been documented.[13,16,60,98,214]

Multiple hypotheses have been proposed to define the mechanism of airway colonization with *P. aeruginosa*. Although several studies have assessed this problem, the exact mechanism of infection and colonization remains investigational. The primary hypothesis for airway infection in CF is altered mucociliary clearance secondary to abnormal salt and water transport. As the normal function of CFTR becomes defined, additional hypotheses have been put forward to explain the mechanism of early airway infection and inflammation. They involve altered epithelial cell receptors for bacteria; abnormal mucins that enhance bacterial binding, impairing airway clearance; and inactivation of epithelial-derived bactericidal activity.

The majority of evidence indicates that the hypothesis of low volume of airway surface liquid hypothesis explains the pathogenic mechanism of lung disease in CF. Dehydration of airway surface liquid and adhesion of mucus to the airway epithelium provide an environment conducive to chronic *Pseudomonas* infection (Fig. 25-3).[454] Depletion of periciliary water decreases ciliary activity, concentrates mucins, and increases adhesion of the mucous layer to the airway surface. Secretion of mucins continues from submucosal glands and goblet cells, producing plugging and airway obstruction. These mucous plaques are poorly cleared from the airway and become the sites of initial infection. Pili extending from the surface of the bacterium are able to bind to mucin.[367] An anaerobic gradient develops within the thickened mucous plugs. *Pseudomonas*, after binding to mucin, is able to penetrate the thickened mucus and grow in an anaerobic environment. *P. aeruginosa* is able to grow in anaerobic conditions because of the production of nitrate reductase, which allows it to cleave oxygen from nitrate.[360] When it is in the anaerobic environment, an alginate polysaccharide is formed. Biofilm-containing macrocolonies of *Pseudomonas* are then established. The established macrocolonies remain within the airway lumen. These macrocolonies are very resistant to antibiotics and host defense and allow chronic infection, inflammation, and airway destruction to occur.[177,296,454]

P. aeruginosa infection of the airway is associated with progressive respiratory impairment and death in most patients with CF. Bacterial colonization and infection of the lower respiratory tract occur early in infants with CF (Fig. 25-4), and airway inflammation often is established at the time the disease becomes clinically manifest.[15] Genotype functional class is an important risk factor in age at initial *Pseudomonas* infection.[333] *P. aeruginosa* infection is intermittent before chronic colonization develops.[137,164,334] Initial isolates generally are antibiotic-sensitive

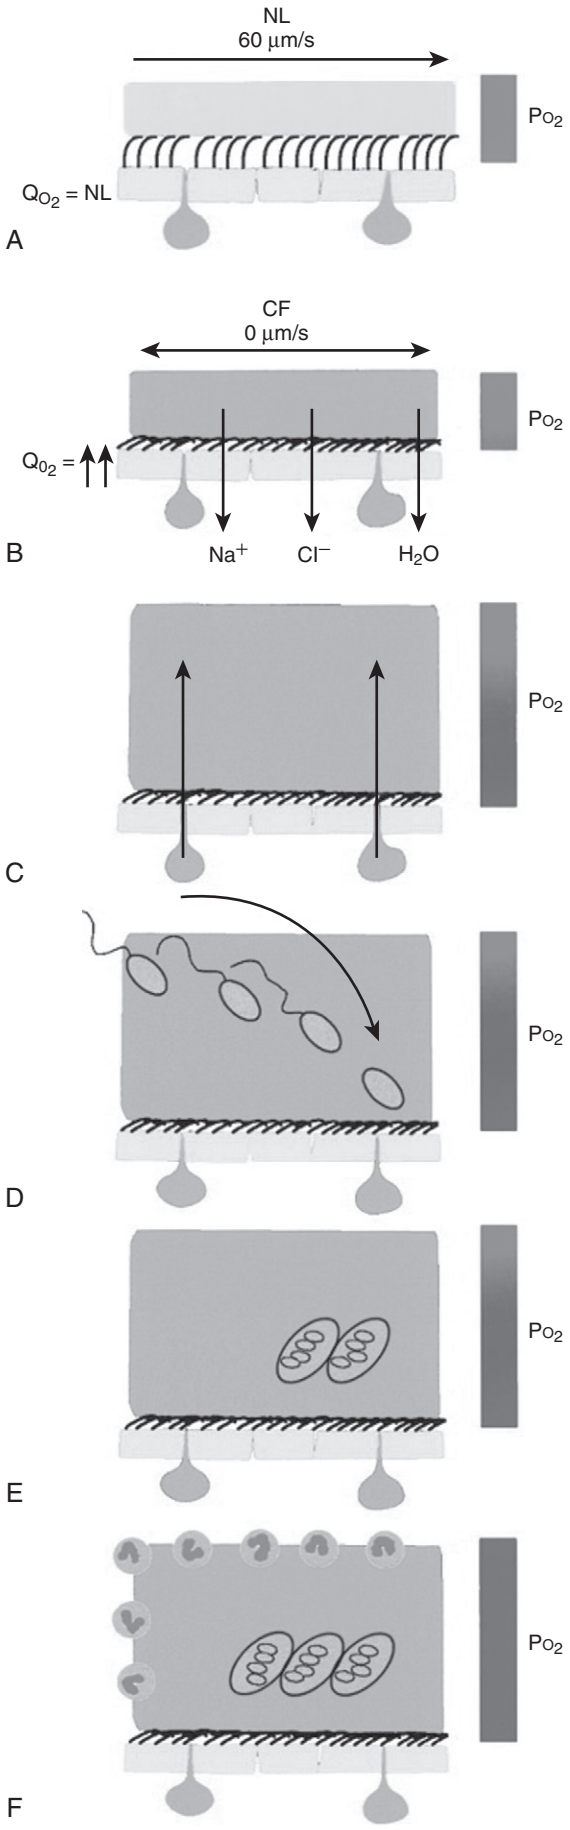

FIGURE 25-3 ■ Schematic model of the pathogenic events hypothesized to lead to chronic *Pseudomonas aeruginosa* infection in airways of patients with cystic fibrosis (CF). **A,** On normal airway epithelia, a thin mucous layer *(light gray)* resides atop the PCL *(clear).* The presence of the low-viscosity PCL facilitates efficient mucociliary clearance (denoted by *vector*). A normal rate of epithelial oxygen (O_2) consumption (QO_2; *left*) produces no O_2 gradients within this thin ASL. **B** through **F,** CF airway epithelia. **B,** Excessive CF volume depletion (denoted by v*ertical arrows*) removes the PCL, mucus becomes adherent to epithelial surfaces, and mucus transport slows or stops (*bidirectional vector*). The increased O_2 consumption *(left)* associated with accelerated CF ion transport does not generate gradients in thin films of ASL. **C,** Persistent mucus hypersecretion (denoted as mucus secretory gland/goblet cell units; *dark gray*) with time increases the height of luminal mucus masses and plugs. The increased CF epithelial QO_2 generates steep hypoxic gradients in thickened mucus masses. **D,** *P. aeruginosa* bacteria deposited on mucus surfaces penetrate actively or passively or both (as a result of mucus turbulence) into hypoxic zones within the mucus masses. **E,** *P. aeruginosa* adapts to hypoxic niches within mucus masses with increased alginate formation and the creation of macrocolonies. **F,** Macrocolonies resist secondary defenses, including neutrophils, setting the stage for chronic infection. The presence of increased macrocolony density and, to a lesser extent, neutrophils renders the now mucopurulent mass hypoxic. (From Worlitzsch D, Tarran R, Ulrich M, et al. Effects of reduced mucus oxygen concentration in airway *Pseudomonas* infections of cystic fibrosis patients. *J Clin Invest* 2002;109:317-25.)

and nonmucoid.[42] In contrast, isolates from patients chronically colonized usually are highly antibiotic-resistant, mucoid, and increased in density.[123,384] As lung disease progresses, the phenotype changes and the bacteria adopt a mucoid biofilm mode of growth.[316] As the organism changes from a nonmucoid to mucoid state, differences in the outer membrane proteins are expressed.[168] In addition, hypermutable strains of *Pseudomonas* are isolated and show greater antibiotic resistance.[285] As *P. aeruginosa* converts from a nonmucoid to mucoid phenotype, several bacterial lipoproteins are produced that induce inflammation.[133]

Local production of cytokines and other proteins in response to bacterial infection may play an important role in modulating chronic airway inflammation.[363] Airway inflammation in CF is characterized by marked neutrophilic infiltration, with release of bioactive lipids, oxygen metabolites, myeloperoxidase, and lysozyme.[131] Proteases (e.g., elastase) derived from neutrophils and bacteria directly damage respiratory epithelium and cleave proteins important in host defense.[394,411] Chronic infection, with retention of the by-products of inflammation, ultimately leads to the severe bronchiectatic changes and derangements of gas exchange characteristic of end-stage CF.

Several in vivo studies have assessed the location of bacterial adherence within the lung of CF patients and the attachment of bacteria to CF and non-CF cells in vitro.[20,415] *P. aeruginosa* is found within the lumen of airways of patients with CF obtained from autopsy specimens.[20] These organisms are observed within the

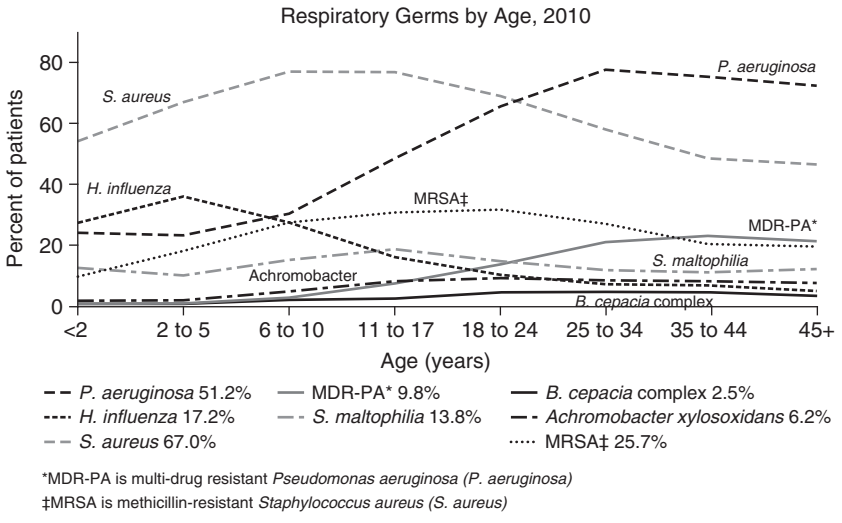

FIGURE 25-4 ■ Age-specific prevalence of pathogens in patients with cystic fibrosis. (From Cystic Fibrosis National Patient Registry, 2000.)

inflammatory exudates of the airway and not within epithelial cells lining the lung or in alveolar spaces. In vitro studies have shown adherence of *P. aeruginosa* in areas of epithelial cell destruction.[303,309,415] No adherence to the apical membrane of intact epithelial cells has been noted, however. In contrast, evidence in cell culture models indicates that defects in CFTR enhance bacterial binding to immortalized airway epithelial cells.[346] A tetrasaccharide (asialo GM_1) is expressed more on CF than on non-CF cells and promotes *P. aeruginosa* binding to the epithelial membrane. Pseudomonal exoproducts such as neuraminidase increase the amount of asialo GM_1 available for bacterial binding and facilitate bacterial adherence to airway epithelial cells.[47,342,348] CFTR itself can act as a receptor for *P. aeruginosa* and initiate an effective innate immune response in the initial stages of infection to clear *Pseudomonas* from the airway.[51] CFTR binding to *P. aeruginosa* induces release of IL-1β, nuclear translocation of nuclear factor-κB (NF-κB), and neutrophil influx. Endocytosis of *Pseudomonas* by the epithelial cells and subsequent clearance of infected epithelial cells by desquamation has been reported.[307,308] In the absence of CFTR, clearance of infection with *Pseudomonas* is impaired.

Mucins also are important in binding bacteria within the airway. Sialylated and neutral forms of mucins bind *P. aeruginosa*.[312] Removal of sialylic acid from mucin by neuraminidase reduces adherence of *P. aeruginosa*. Mucus dehydration can lead to increased concentration of mucins, decreased pH, and a reduction in glutathione, which decreases mucus viscoelasticity.[340] Decreased bicarbonate secretion results in mucin cross linking by calcium.[125] Polymeric macromolecules within the gel matrix reduce pore size from 500 nm to 150 nm, immobilizing bacteria within the mucus and inhibiting neutrophil migration and clearance.[76] The concentrated mucus impairs neutrophil migration, promotes an anaerobic environment, and reduces mucociliary transport. Mucin, a component of mucus, is decreased in CF, and its decreased content may promote development of infection.[341]

In contrast to the hypothesis of low volume of airway surface liquid discussed in detail earlier, the "high salt" theory proposes that CFTR maintains low concentration of salt in airway lining fluid. In the absence of CFTR, high concentrations of salt inactivate the secreted antimicrobial substances on airway surfaces.[458] Airway epithelial cells are vital in maintaining a pathogen-free environment within the airway. Smith and colleagues[370] showed that a monolayer of airway epithelial cells was able to kill bacteria when placed on their apical surface. In contrast, CF epithelia were unable to clear the bacterial load. Surface fluid washed from the normal cells showed bactericidal activity; however, fluid from the CF monolayer lacked bacterial killing properties. Goldman and colleagues[155] duplicated the results of this study using a different model. They implicated a human defensin, hBD-1, as the primary agent responsible for bacterial killing. The defensins are low-molecular-weight proteins produced by epithelial cells cytotoxic for bacteria and thought to be salt-sensitive. Many studies have not supported these early observations[36] but rather favor the high viscosity of the airway surface fluid, which hinders mucociliary clearance.

Oxidant stress plays a role in tissue injury observed in CF. Defective CFTR produces a redox imbalance in respiratory epithelial cells and extracellular fluid. Reactive oxygen species are important in killing bacteria and are generated by phagocytic cells and the respiratory epithelium. Oxidants are produced from activated phagocytes, metabolic pathways, inhaled oxidants, and bacteria.[54] Increased oxidant production alters ion transport and increases secretion of mucins.* Excessive oxidant production can cause tissue injury. Increased oxidant production by neutrophils has been proposed as a mechanism of airway injury. Markers of reactive oxygen species increase during acute pulmonary exacerbations and improve with treatment but do not normalize.[250,409] The continued presence of reactive oxygen species after successful treatment with antibiotics, supports the ongoing

*References 52, 79, 194, 275, 399, 401.

production of reactive oxygen species and chronic inflammation within the airways. Reactive oxygen species can further effect NF-κB transcription of proinflammatory genes, increasing the inflammatory response.[428] Neutrophils migrating into the airway lumen release large amounts of reactive oxygen species, including superoxide anion, hydrogen peroxide, and hydroxyl free radicals. These reactive species are generated by activation of nicotinamide adenine dinucleotide phosphate (NADPH). Continued interactions with bacterial products and inability to engulf bacteria lead to exaggerated production of or pro-oxidative species in the airway lumen, airway injury, and amplification of the inflammatory response.[141] One study has examined the activity of NADPH and myeloperoxidase with production of chloramines between CF and non-CF subjects.[448] Significant differences between groups were observed for myeloperoxidase activity and chloramine release. Myeloperoxidase activity and chloramine release were increased in subjects with CF. Treatment of CF neutrophils with amiloride reduced oxidant generation, suggesting that altered intracellular ion concentrations or pH may regulate myeloperoxidase activity. Other investigators have suggested alternatively that the circulating neutrophils may be primed to respond to a phagocytic stimulus and that these differences in oxidant generation represent increased neutrophil activity.[163,322]

An intracellular imbalance in oxidant metabolism has been proposed for airway epithelial cells in CF.[358] Airway surface liquid in CF is characterized by lower levels of glutathione and nitric oxide. Antioxidants are produced by enzymatic and nonenzymatic pathways.[54] Mucins, reduced glutathione, α-tocopherol, and metal-binding proteins function in the airway as antioxidants. The cysteine residues and carbohydrates of mucin account for its antioxidant properties.[82] Secretion of mucins is increased with oxidative stress; however, dehydration of mucins may impair its ability to scavenge reactive oxidative metabolites. Glutathione is important in regulating inflammation related to oxidative stress. Glutathione is reduced in airway surface liquid either from increased consumption or secondary to CFTR dysfunction.[224] Glutathione is found in large amounts in airway lung fluid from normal patients[53]; however, it is reduced in patients with CF.[391] CFTR may alter glutathione transport, impairing defense to oxidant injury. Low levels of glutathione are observed in CF knockout mice, supporting observations in humans.[426] Reduced intracellular concentrations of glutathione affect hydrogen peroxide content of airway cells and increase NF-κB production, contributing to airway inflammation. Thus, increased production of reactive oxygen species from neutrophils and impaired antioxidant biosynthesis associated with mutant CFTR creates an environment within the airway for excessive inflammation and cellular injury. Production of cell adherence molecules and inflammatory cytokines is intact in patients with CF.[104,203] Defects in bacterial opsonization, reduction in anti-inflammatory cytokines, and proinflammatory effects of bacterial DNA have been reported. Impaired phagolysosomal function and decreased respiratory burst have been found in neutrophils in CF with upregulation of Toll-like receptor (TLR)4 and downregulation in TLR2. These abnormalities would be expected to reduce the ability of neutrophils to clear bacteria.[24,262] Inflammation and infection can increase intracellular Ca^{2+} and affect the immune response mediated by airway epithelial cells and T-helper cells. Increased intracellular Ca^{2+} in CF mice helper T-cells affect gene expression and favor a Th2 differentiation rather than the Th1 needed for bacterial clearance.[268] Altered T-helper lymphocytes impair macrophage activation for bacterial killing. Humoral antibody responses are normal; however, increased elastase in the CF airway can alter opsonic receptors, impairing phagocytosis. Large amounts of elastase are present in lavage fluid from airways of patients with CF, overwhelming the normal antiprotease activity. This condition can lead to local impairment in phagocytosis of bacteria within the airway lumen, contributing to bacterial persistence.

Proinflammatory mediators are elevated in BAL fluid from young patients with CF, as are macrophages expressing intracellular cytokines.[198,269,459] Increased numbers of neutrophils and IL-8 in BAL fluid are seen in bacterial culture–negative and bacterial culture–positive infants with CF in contrast to controls.[181,444] Proinflammatory mediators IL-1, IL-2, tumor necrosis factor-α, and IL-8 are markedly elevated in children with advanced disease.[169,181,444] In contrast, some anti-inflammatory cytokines (e.g., IL-10) are found in reduced amounts in BAL from patients with CF. These observations have prompted some investigators to assess production of IL-10 from bronchial epithelial cells in normal subjects and subjects with CF.[30] Bronchial epithelial cells from normal individuals produce significantly greater amounts of IL-10 than cells of subjects with CF. NF-κB is a transcription factor for several proinflammatory mediators and is activated persistently in CF. Inhibitors to NF-κB, including IL-10, are downregulated.[102,357,427,437]

Enhanced intracellular Ca^{2+} signaling in response to infection and inflammation in both airway epithelial and immunomodular cells may account for the hyperinflammatory response noted in CF.[319,325] Both phases of Ca^{2+} release, either by Ca^{2+} influx or endoplasmic reticulum release, can upregulate NF-κB and production of proinflammatory cytokines. Chronic airway inflammation and infection increase endoplasmic reticulum Ca^{2+} stores, enhancing the inflammatory response. Therefore the CF gene defect may result in an inability to control airway inflammation after exposure to repeated infections altering the innate and immune responses to specific pathogens. Although the understanding of this disease pathogenesis is incomplete, airway damage that occurs from excessive inflammation and chronic infection remains a target for new therapeutic modalities.

MICROBIOLOGY

Epidemiology of Pathogens

Most commonly, patients with CF are infected with classic pathogens, including *Staphylococcus aureus*, nontypeable *Haemophilus influenzae*, and *P. aeruginosa*.[8,46,149,253] A few patients may be infected with *Burkholderia cepacia*

complex, which can be particularly virulent and, in some patients, associated with increased morbidity and mortality.[77,159,331] More recently, potentially emerging pathogens, such as methicillin-resistant *S. aureus* (MRSA), *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, nontuberculous mycobacteria (NTM), mold species (primarily *Aspergillus* spp.), and, more recently, *Scedosporium* spp., are being reported. Additional potential pathogens include *Ralstonia* and *Pandoraea* spp.[68,227] As described in more detail subsequently, the link between these pathogens and lung disease is not fully elucidated.

The etiologies behind these emerging pathogens are multifactorial. The average life expectancy of patients with CF has increased significantly during the past 2 decades from 27 years in 1986 to 38.3 years in 2010.[88] Patients with CF are treated frequently with prolonged courses of antimicrobial agents, including oral, intravenous, and aerosolized agents, placing selective pressure on their flora and leading to increased resistance.[41,43,87] Evidence of health care–associated acquisition of some pathogens, including *B. cepacia* complex, *P. aeruginosa*, and MRSA, is described subsequently. Finally, during the past 2 decades, detection of many potential pathogens has improved as clinical microbiology laboratories processing CF specimens use several selective media and fully speciate non–lactose-fermenting, gram-negative bacilli as described subsequently.[149,170,398,466]

Age-Specific Prevalence of Pathogens

The U.S. Cystic Fibrosis Foundation has maintained an annual Patient Registry since 1962.[134] The age-specific prevalence for CF pathogens in the United States as reported to this registry in 2010 is shown in Figure 25-4.[88] During the first two decades of life, *S. aureus* is the most common pathogen and is harbored by approximately 70 percent of children and adolescents. Nontypeable *H. influenzae* is a less prevalent pathogen and is cultured from the respiratory tracts of 15 percent of children with the highest prevalence in children 2 to 5 years old. Over time, *P. aeruginosa* becomes the most prevalent pathogen, but it can be recovered from 30 percent of infants. Approximately 70 percent of American patients with CF are infected with *P. aeruginosa* by the time they reach 18 years of age, at which point *P. aeruginosa* becomes more prevalent than *S. aureus*. Overall, *Burkholderia* spp.[225] are recovered from approximately 3 percent of patients with CF. During the late 1990s, the Cystic Fibrosis Foundation began to collect data on the prevalence of MRSA, *S. maltophilia*, and *A. xylosoxidans*. As shown in Figure 25-4, these organisms are more common than *B. cepacia* complex and are harbored primarily by adolescent and adult patients. As noted in patients without CF, MRSA has become increasingly common.[323]

ROLE OF THE CLINICAL MICROBIOLOGY LABORATORY

Ongoing communication between the clinical microbiology laboratory and the CF care team is crucial to ensure that appropriate methodologies are in place to provide appropriate care, to support effective infection control, and to further understanding of the epidemiology of pathogens in CF.[350] Every 5 years, the executive committee of the U.S. Cystic Fibrosis Foundation conducts site visits of accredited CF care centers and meets with the director of the clinical microbiology laboratory in efforts to ensure that standardized practices are in place.[349] In addition, a survey determined that most clinical laboratories processing CF specimens were using selective media and speciating all gram-negative bacilli,[466] which may include molecular identification strategies.

Specimen Processing

Respiratory tract specimens from patients with CF, including specimens obtained after lung transplantation, should be physically and electronically indicated as "CF specimens" to ensure proper processing by the clinical laboratory. Timely transport optimizes recovery of pathogens; ideally, specimens should be received by the laboratory within 3 to 4 hours of collection or stored at 4° C (39.2° F) and processed within 24 hours. Sputum is the ideal specimen, and at least 1 mL should be collected to ensure an adequate volume is available for plating on selective media. Sputum can be Gram stained to determine if a specimen contains bacteria and neutrophils rather than epithelial cells. Oropharyngeal cultures often are obtained in children too young to expectorate, but these cultures may not be concordant with specimens obtained from the lower airway.[332] BAL specimens generally are reserved for research protocols, lung transplant recipients, or patients with atypical courses who cannot produce sputum. More recently, induced sputum has been promoted to assess the lower respiratory tract flora of patients with CF who cannot expectorate.[175,290]

Selective Media

Selective media are needed to isolate specific pathogens, although the use of these media is costly and time-consuming. Current recommendations for selective media are shown in Table 25-3. *S. aureus* strains from patients with CF may be thymidine-deficient and require mannitol salt agar for growth.[349] Detection of *B. cepacia* complex is markedly enhanced by the use of oxidative fermentative bacitracin polymyxin B lactose (OFBPL) agar or *B. cepacia* selective media.[149,170] Multicenter studies conducted by the Centers for Disease Control and Prevention in the 1980s showed that the use of selective media improved the yield of *Burkholderia* spp. from patients with CF.[396] In addition, specimens can be plated on mycosel agar to identify *Aspergillus* spp., although this mold grows well on blood agar as well as OFBPL. Oropharyngeal swabs from nonexpectorating patients also should be plated on selective media.[365] If NTM are suspected, sputum should be stained for acid-fast bacilli and processed using an additional decontamination step to prevent overgrowth by *P. aeruginosa*.[440] This decontamination step may kill NTM present in low concentrations, however.[21] Quantitative cultures of specimens from sputum are reserved for research purposes.

TABLE 25-3 **Recommended Media and Processing for Recovery of Cystic Fibrosis Pathogens**

Organism	Recommended Media or Processing*,†
Staphylococcus aureus	Mannitol salt agar
	Columbia/colistin–nalidixic acid agar
Haemophilus influenzae	Horse blood or chocolate agar (supplemented or not with 300 mg/L bacitracin) incubated anaerobically
Pseudomonas aeruginosa	MacConkey agar
Burkholderia cepacia complex	OFPBL agar, PC agar, BCSA
Stenotrophomonas maltophilia	MacConkey agar, VIA agar
	DNase agar confirmatory media or biochemical or molecular identification
Achromobacter xylosoxidans	MacConkey agar
	Biochemical identification assay
Mycobacterial spp.	NALC-NaOH and oxalic acid decontamination step
Yeast	Mycosel agar‡
Other gram-positive organisms	Sheep blood agar supplemented with neomycin and gentamicin (streptococcal selective agar)
Other gram-negative organisms	MacConkey agar

*Detection of some pathogens may be enhanced by prolonging incubation for 4 days to allow slow-growing colonies to become apparent.
†All media are commercially available.
‡Aspergillus spp. and other molds do not grow well on Mycosel, but do grow well (although not selectively) on many of the media used for cystic fibrosis specimens, especially OFPBL. Standard biochemical and phenotypic methods should be used for confirmation of the identification of molds.

Antimicrobial Susceptibility Testing

The optimal methodology for antimicrobial susceptibility testing for mucoid and nonmucoid strains of *P. aeruginosa* has been elucidated. In studies of 500 multidrug-resistant strains of *P. aeruginosa* from patients with CF, five different antimicrobial susceptibility testing methods were compared: a reference microbroth dilution assay, Kirby Bauer disks, E-tests, and the automated commercial systems Vitek and Microscan. The agar-based diffusion methods (i.e., Kirby Bauer disks and the E-test) proved most accurate in contrast to the reference methods.[44,345] Vitek and Microscan, the commercial systems, had unacceptably high rates of very major (i.e., false-susceptible) and major (i.e., false-resistant) errors.[45] The Clinical Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards) endorses the use of antibiotic-impregnated disks or reference broth microdilution assays to determine the susceptibility of multidrug-resistant strains of *P. aeruginosa* isolated from patients with CF.[272]

An intriguing concept in susceptibility testing is the potential role of susceptibility testing of bacteria grown in biofilms. As described in more detail subsequently, chronic lung infection in CF is thought to reflect a biofilm mode of growth containing bacteria in stationary phase that do not express the antibiotic targets present in log phase bacteria.[78] In vitro studies have shown that the minimal inhibitory concentration (MIC) of log phase bacteria tested in conventional susceptibility testing assays can be very different from the MIC of bacteria growing in stationary phase in biofilms.[172] Log phase–grown *P. aeruginosa* are resistant to macrolide antibiotics (MIC ≥128 μg/mL), whereas *P. aeruginosa* grown in biofilms are susceptible to these agents (MIC_{50} 2 μg/mL).[265] Studies are ongoing to compare the outcomes of pulmonary exacerbations treated using the results of conventional susceptibility testing versus the results from biofilm susceptibility testing.

Molecular Methods

Molecular diagnostics remain an important component in the accurate identification of pathogenic bacteria in respiratory specimens of patients with CF. When conventional culture methods fail to yield a definitive result, molecular testing performed on a cultured isolate is a rapid and cost-effective strategy for confirmation of suspected organisms. The most common molecular microbiology methods for bacterial identification use sequencing of the 16S rRNA gene.[25,233] Real-time PCR has also been used to detect and quantify known pathogens of interest in CF.[461] The role of microarrays and next-generation sequencing in the clinical molecular microbiology laboratory setting is still developing, but recent studies in the CF population suggest significant information regarding organisms that are not routinely cultured could be obtained using these methods, including more thorough fungal characterization.[81,96,366]

SPECIFIC CYSTIC FIBROSIS PATHOGENS

Viral Pathogens

Numerous studies have evaluated the role of nonbacterial infections with pulmonary exacerbations in CF. A clear correlation between respiratory viral infection and exacerbations of lung disease has been shown in most of these reports.* Viral lower respiratory tract infections occur more often in younger children and are associated with increased pulmonary disease in 40 percent of cases in CF.[2,419] Respiratory syncytial virus (RSV) has been identified most often with CF pulmonary exacerbations; however, influenza, adenovirus, parainfluenza virus, rhinovirus, picornavirus, and human metapneumoviruses also have been reported.[419] Respiratory viruses are isolated from patients with CF requiring

*References 2, 114, 142, 179, 284, 289, 302, 310, 314, 389, 435, 455.

hospitalization, and infection is associated with increased morbidity rates. Infants with CF infected with RSV can experience prolonged hospitalizations, mechanical ventilation, and supplemental oxygen at hospital discharge.[2] Severe viral infections in infants with CF were reported in 31/80 children diagnosed by newborn screening. Half of the children hospitalized had a respiratory virus identified at the time of hospitalization, and RSV infection accounted for hospitalization in 7 of the 31 children.[12]

Two studies have reported prolonged bronchiolitis-like syndromes in infants younger than 6 months of age.[145,231] These infants required intensive respiratory therapy, including bronchodilators, chest physiotherapy, and mechanical ventilation. Increased hospitalization was observed for children with CF who were infected with RSV in another study of children younger than 3 years of age.[171] Although prolonged hypoxia and respiratory failure were not observed, pulmonary function was markedly decreased after hospitalization and persisted for several months after infection.[171] Studies in older children with CF have reported reduction in pulmonary function, clinical scores, and radiographic scores and increased hospitalization after viral infection.[73,289,374,435,447] These studies show that infection with respiratory viruses results in clinical deterioration, hospitalization, and decreases in lung function.

Mechanisms to explain the enhanced disease observed with respiratory viral infections are being investigated. Normal airway epithelia use an adenosine-regulated pathway to maintain periciliary fluid volume by regulation of sodium absorption and chloride secretion. In a CF model, this regulation can be normalized by phasic motion simulating movement of the lung. Periciliary volume is restored to normal by release of adenosine triphosphate into the periciliary liquid and activation of alternative chloride channels. Viral infections, such as RSV, upregulate the extracellular adenosine triphosphatase activity, reducing periciliary fluid volume. Reduction in periciliary liquid volume promotes mucous stasis and plugging.[404] Other investigators have shown impaired innate defense manifested by reduced production of nitric oxide and impaired IFN-γ signaling pathway.[463,464]

The interrelationship between the acquisition of *P. aeruginosa* and viral respiratory infection is unclear. Increased colonization with *Pseudomonas* has been observed during the respiratory viral season,[193] and infection with *Pseudomonas* has been associated with hospitalization for viral respiratory illness. Antipseudomonal antibodies have been reported to increase after having RSV infection, and new infection with *Pseudomonas* has been observed during an acute respiratory illness.[73,302] Other investigators have not observed any change in bacterial infection or change in colonization associated with viral respiratory infection.[284] In cell culture models, RSV acts as a coupling agent between *P. aeruginosa* and enhances attachment to respiratory epithelial cells.[420] Petersen and colleagues[302] and Ong and associates[289] reported more severe pulmonary disease with viral infection in the presence of *P. aeruginosa* colonization, but Przyklenk and coworkers[310] found no correlation. Synergism between bacteria and respiratory virus infection was suggested by Przyklenk and coworkers[310] after an increase in the number of bacterial colony-forming units was found in sputum of subjects with CF. Hordvik and associates[179] and Efthimiou and coworkers[114] noted that patients with CF and severe pulmonary disease recovered slowly from viral infection. The underlying severity of lung disease was crucial in predicting response to viral respiratory infection.

Nontypeable *Haemophilus influenzae*

H. influenzae frequently is the earliest pathogen isolated from patients with CF, and it is most prevalent in the CF population during the first 5 years of life. The advent of the *H. influenzae* vaccine has not had an impact on the prevalence of this organism because patients with CF harbor nontypeable strains. Generally, *H. influenzae* is susceptible to a wide variety of agents and is amenable to treatment. However, recent studies suggest that more than 20 percent of young patients with CF are infected with *H. influenzae*, with some antibiotic resistance detected in current strains.[55] Despite the frequent recovery of this organism from infants and children, the impact of this organism on the clinical course of CF has been difficult to assess because of the frequent occurrence of coinfection with other pathogens.

Staphylococcus aureus

Methicillin-susceptible *S. aureus* (MSSA) and MRSA are increasing in prevalence. Patients generally retain the same clone of MSSA for their lifetime.[38,356] Data from the Cystic Fibrosis Patient Registry showed that the overall prevalence of MSSA increased from 37 percent in 1995 to 67 percent in 2010.[88] Similarly, MRSA increased from 0.1 percent in 1995 to 25.7 percent in 2010, although the prevalence varied substantially from center to center (range per center, 5% to 50%). The causes for this variability are unclear but could reflect different laboratory practices, different clinical practices, or regional differences in community-acquired MRSA. Although MRSA generally infects older patients, it usually is persistent[323] and can be associated with deterioration in both pediatric and adult patients.[255,407] A more recent report compared the outcomes of patients with MSSA versus MRSA and showed that children (<18 years of age) and adults infected with MRSA had worse lung function, more hospitalizations, and more antibiotic use.[323]

Recent hospitalization has been shown to be a risk factor for MRSA, suggesting nosocomial acquisition,[152] but the relative importance of community-acquired MRSA strains (mecA type IV and V) has not been fully elucidated. A more recent case series has suggested that community-acquired MRSA strains expressing Panton-Valentine leukocidin can be associated with increased morbidity, including focal pulmonary infiltrates with cavitary lesions and a greater decline in lung function.[116]

Pseudomonas aeruginosa

P. aeruginosa is the most common and important pathogen in patients with CF. Initial strains are nonmucoid, antibiotic-susceptible strains that express pili, flagella, and more highly acylated lipid A component of lipopolysaccharide.[161] *P. aeruginosa* also produces virulence factors, including exotoxin A, exoenzyme S, leukocidin, phospholipase C, elastase, and alkaline protease, which contribute to the pathogenesis of sepsis, acute lung infections, and bacteremia.[57,377,402] These factors may be chemotactic stimuli for neutrophils, and exotoxins may increase the viscosity of secretions and impair ciliary clearance and cause small airway obstruction and ultimately lung destruction.

Over time, *P. aeruginosa* adapts to the CF lung and undergoes genetic and phenotypic alterations. *P. aeruginosa* initially attaches to solid surfaces (e.g., mucin or respiratory epithelial cells), using flagella and type IV pili.[78] Attachment activates genes that synthesize extracellular polysaccharide (alginate),[99] which confers the mucoid phenotype of *P. aeruginosa* unique to chronic infections in CF.[160] Strains associated with chronic infections lack pili, lack flagella, and undergo structural changes in lipopolysaccharide. These changes may render *P. aeruginosa* more resistant to host defenses, including defensins and the innate inflammatory response. The *lasR-lasI* system (quorum-sensing genes) promotes the initial formation of microcolonies, which differentiate into alginate-encased mature biofilms.[78] Bacteria in biofilms avoid ciliary clearance, evade phagocytosis, and are antibiotic-resistant.[368] Biofilms are the proposed mechanism by which *P. aeruginosa* is able to infect the CF airway chronically and avoid eradication by host defenses and by antimicrobial agents. The CF lung can harbor very high concentrations of *P. aeruginosa*—10^8 to 10^9 organisms per gram of sputum may be present.[450]

In 2010, the CF Registry reported that 35.3 percent of patients with CF younger than 18 years of age were infected with *P. aeruginosa*.[88] Infection with *P. aeruginosa* is associated with increased morbidity and mortality rates caused by recurrent pulmonary exacerbations and a gradual deterioration in lung function.[202,293] Children who are infected with *P. aeruginosa* are more likely to have cough and lower chest radiograph scores than are uninfected children.[183] Investigators have shown that infants younger than 2 years of age infected with *S. aureus* and *P. aeruginosa* have worse pulmonary function, chest radiograph scores, and 10-year survival rates than do uninfected children.[3] The mucoid phenotype of *P. aeruginosa* is associated with a more rapid decline in lung function.[294] Multidrug-resistant *P. aeruginosa* (MRPA) was identified in 19 percent of all patients with CF in 2010. MRPA isolates are defined as resistant to all antibiotics evaluated in two or more of the following groups: aminoglycosides, fluoroquinolones, and β-lactams.[221] Infection with MRPA as opposed to *P. aeruginosa* has been shown to cause more rapid decline in pulmonary function[220] and increasing the likelihood of death or lung transplantation.[223] Additional studies have linked poor patient prognosis to a specific MRPA strain, as in the cases of the Liverpool epidemic strain and the Australian epidemic strains.[5,113,277,279]

Burkholderia cepacia Complex

Infection with *B. cepacia* complex and the associated "cepacia syndrome" was reported first in 1979 among adolescent Canadian patients with CF.[188,397] The cepacia syndrome is characterized by a virulent course, high fevers, bacteremia, rapid deterioration in lung function, and early death. Generally, patients with CF do not have bacteremia caused by other pathogens. Different clinical courses can be associated with *B. cepacia* complex, however, including transient colonization, a gradual decline in lung function, or the virulent cepacia syndrome.

Through a series of genetic and phenotypic studies, researchers have discovered that *B. cepacia* is actually a complex of several different species, previously called *genomovars*, which are indistinguishable phenotypically but distinguishable genotypically.[69] The genomovars of the *B. cepacia* complex are shown in Table 25-4, but additional genomovars are likely to be described.[69,422,423,430] Several international investigators have described the epidemiology and clinical courses associated with different genomovars, although these studies usually involved a single strain and might not be generalized to all strains of a given genomovar.[226,235,383] Most CF isolates are *Burkholderia cenocepacia* (genomovar III) or *Burkholderia multivorans* (genomovar II). The former may be associated with a more rapidly progressive clinical course,[230] whereas *B. multivorans* is more likely to be associated with transient colonization.[235] Patient-to-patient transmission and clinical deterioration can be associated with *B. multivorans*, however.[226] Most recently, an outbreak of *Burkholderia dolosa* (genomovar VI) occurred, and this newly described genomovar was associated with increased morbidity and mortality rates.[196]

Virulence factors for *Burkholderia* spp. include multidrug resistance, the ability to form biofilms, the ability to reside intracellularly, and the ability to spread from patient to patient potentially via the cable pilus[393] or the *B. cepacia* epidemiologic strain marker.[235] Many outbreak

TABLE 25-4 **Members of the *Burkholderia cepacia* Complex**

Species (Genomovar)	Binomial Designation
I	*B. cepacia*
II	*B. multivorans*

IV	*B. stabilis*
V	*B. vietnamiensis*
VI	*B. dolosa*
VII	*B. ambifaria*
VIII	*B. anthina*
IX	*B. pyrrocinia*

strains do not express these transmission factors, however. Studies are ongoing to unravel potential environmental reservoirs of *Burkholderia* spp.

Stenotrophomonas Maltophilia

S. maltophilia, an intrinsically multidrug-resistant, gram-negative bacillus, is a well-known hospital-acquired pathogen in non-CF patients and is isolated with increasing frequency from the respiratory tract of patients with CF. The overall prevalence of this organism in patients with CF is 13.8 percent (range 0 to 27% in individual centers).[88,97] In a multicenter, randomized, placebo-controlled study of aerosolized tobramycin conducted in 520 patients 6 years of age and older with CF, the baseline prevalence of *S. maltophilia* determined by a core laboratory was 10.7 percent,[46] whereas the national rate among comparably aged patients reported to the Cystic Fibrosis Patient Registry was 2.9 to 3.9 percent, suggesting that many clinical laboratories were failing to identify this potential pathogen. Transient colonization also seems to be a common occurrence; Demko and colleagues[97] reported that 50 percent of patients with CF at their center had only a single positive culture for this microorganism. Increased use of antibiotics has been shown to be a potential risk factor for acquisition of *S. maltophilia*.[241,400]

The role of this organism as a pathogen in CF is still being investigated. Case-control studies have not shown that *S. maltophilia* has a significant impact on lung function or mortality.[156,241] In contrast, Demko and colleagues[97] found that the 5-year survival of patients with *S. maltophilia* ($n = 211$) with severe lung function at initial isolation of this organism was 40 percent in contrast to patients without *S. maltophilia* ($n = 471$), whose 5-year survival was 72 percent.

Achromobacter xylosoxidans

The clinical significance of *A. xylosoxidans* in CF also is unclear. In 1996, the first year this organism was reported to the Cystic Fibrosis Patient Registry, 2.7 percent of patients harbored this multidrug-resistant, gram-negative bacillus.[87] In 2010, *A. xylosoxidans* was found in 6.2 percent of patients.[88] As described for *S. maltophilia*, however, the nationally reported prevalence most likely is underestimated; 8.7 percent of participants in the aerosolized tobramycin trial had positive cultures for *A. xylosoxidans*.[46] Further complicating the epidemiology of this potentially emerging pathogen are the observations that *A. xylosoxidans* may be misidentified as some other non–lactose-fermenting, gram-negative bacilli, and that *P. aeruginosa*, *B. cepacia* complex, and *S. maltophilia* may be misidentified as *A. xylosoxidans*.[347] In addition, the impact of this organism is difficult to assess fully because *A. xylosoxidans* generally is cultured from patients concomitantly infected with other CF pathogens, especially *P. aeruginosa*,[219] but an association has been found between *A. xylosoxidans* and pulmonary exacerbations.[110,124]

Aspergillus Species and *Scedosporium* Species

Patients with CF frequently are colonized with *Aspergillus* spp.; 24.5 percent of participants in the inhaled tobramycin trial indicated they had positive cultures for this mold.[42] Oral and aerosolized antimicrobial agents are risk factors for colonization with *Aspergillus* spp.[22,315] Recent findings also confirmed the formation of biofilms and increased antifungal drug resistance by *A. fumigatus*.[362]

Of patients with CF, 2 to 10 percent develop APBA, which can be associated with a dramatic loss of lung function.[117,146,243,267] The diagnosis of ABPA can be difficult to establish because of variability in the application of standardized diagnostic criteria, confusion regarding these criteria, and limited recognition by physicians. This immunologically mediated syndrome is marked by a brisk IgE response, specific antibody to *Aspergillus fumigatus*, peripheral eosinophilia, and symptoms of reactive airway disease. Short-lived pulmonary infiltrates may be noted on chest radiograph. Although *Aspergillus* spp. do not normally invade the parenchyma, the airways can become impacted with mucus-containing fibrin, eosinophils, and mononuclear cells, which can cause airway obstruction and bronchiectasis.[117]

A workshop sponsored by the Cystic Fibrosis Foundation sought to further understanding of the diagnostic criteria needed for ABPA in CF.[387] This committee established minimum criteria for the diagnosis, which included (1) new clinical deterioration not attributable to another cause; (2) IgE greater than 500 IU/mL; (3) immediate skin reactivity to *Aspergillus* antigen or IgE antibody to *A. fumigatus*; and (4) precipitants or IgG against *A. fumigatus*, new chest radiograph, or new chest CT findings.

Scedosporium spp. can be isolated from the lungs of patients with CF, but the clinical significance of this microorganism is unknown. In the aerosolized tobramycin trial, 2.4 percent of patients harbored saprophytic fungi,[46] and in a single center, 8.6 percent of 128 patients followed for more than 5 years were colonized or infected with *Scedosporium apiospermum*.[65] Although previous studies implicated *S. apiospermum* in ABPA-like reactions,[65] additional selective media beyond routine culture methods would be necessary to recover most *Scedosporium* spp. and obtain more accurate infection rates.[29]

Nontuberculous Mycobacteria

Since the early 1990s, appreciation has been increasing that NTM may be pathogens in patients with CF. Olivier and colleagues[288] conducted a natural history study of NTM in patients with CF in 21 CF centers from 1993 to 1997. Using standardized mycobacteriologic methods,[441] these investigators found that the overall prevalence of colonization and infection with NTM was 13 percent. *Mycobacterium avium* complex (MAC) and *Mycobacterium abscessus* were most common, representing 72 percent and 16 percent of isolates, respectively. Patients with NTM were older and had better lung function, a lower prevalence of *P. aeruginosa*, and a higher prevalence of *S. aureus* than patients without NTM,

suggestive of a "healthy survivor effect." Risk factors for NTM may include geographic proximity to large bodies of water,[288] ABPA, and steroid therapy.[271]

In an individual patient, determining if NTM is colonizing the lung or causing disease can be difficult. Signs and symptoms of mycobacterial disease are nonspecific and may be consistent with CF pulmonary exacerbations. Radiographic signs generally are nonspecific, but small nodules in the lung periphery or progressive "tree and bud" lesions may be noted on high-resolution CT scan.[286] Patients with positive acid-fast bacillus smears and two or more positive cultures are more likely to be infected than colonized with NTM.[7] Patients harboring *M. abscessus* are more likely to fulfill the American Thoracic Society diagnostic criteria for NTM disease than are patients harboring MAC.[162,287] In a study to assess the clinical impact of NTM, 60 incident-case patients with positive NTM cultures were followed for 15 months and did not have increased morbidity in contrast to control patients with negative cultures.[287] Because this was a short duration of follow-up, further studies are needed to determine if NTM causes progressive deterioration in lung function and, if so, the optimal therapy. More recent studies focusing on *M. abscessus* have also failed to identify risk factors for infection.[431]

TREATMENT OF PATHOGENS IN CYSTIC FIBROSIS PATIENTS

A cornerstone of CF care is the aggressive use of oral, intravenous, and aerosolized antibiotics. The increasing longevity of patients with CF has paralleled the development of effective antibiotics. Antibiotics may be used during several stages of CF lung disease: (1) to prevent acquisition of pathogens, most commonly MSSA; (2) to eradicate initial acquisition of pathogens, most commonly *P. aeruginosa*, in efforts to prevent or delay chronic infection; (3) to treat pulmonary exacerbations caused by classic CF pathogens; (4) to treat patients infected with *P. aeruginosa*, as long-term suppressive therapy; and (5) to treat emerging multidrug-resistant pathogens.

Prophylaxis to Prevent Acquisition of *Staphylococcus Aureus* and *Pseudomonas Aeruginosa*

Few studies have been conducted on antibiotic prophylaxis in patients with CF, and these studies have focused mostly on *S. aureus*. The rationale for this strategy is to prevent *S. aureus* infection and to delay acquisition of *P. aeruginosa*.[371,372] From 1985 to 1992, British investigators studied 42 newly diagnosed infants randomly assigned to 12 months of flucloxacillin versus standard care.[23,436] Infants treated with flucloxacillin had fewer infections with *S. aureus* and fewer hospitalizations, but both groups had similar pulmonary function. In a placebo-controlled trial conducted in the United States, 119 patients newly diagnosed with CF (mean age, 16 months) were randomly assigned to receive cephalexin or placebo for 5 to 7 years.[390] No significant differences were found in pulmonary function, the number of pulmonary exacerbations, nutritional status, or chest radiograph scores in the two groups. In contrast, patients treated with cephalexin had decreased incidence of infection with *S. aureus* but increased incidence of infection with *P. aeruginosa*. Similarly, an analysis of the German national database showed that patients receiving antistaphylococcal agents had increased acquisition of *P. aeruginosa* and no improvement in lung function.[317]

Antistaphylococcal prophylaxis, although practiced in the United Kingdom in infants, has not been widely endorsed in the United States because of concerns about the emergence of resistance, the increased risk for acquiring *P. aeruginosa*, and the lack of impact on lung function. The different findings in these studies may reflect the different agents studied because cephalexin has a broader spectrum of activity than flucloxacillin, different durations of therapy, or both. In an era of increasing prevalence of MRSA, strategies to prevent MSSA may prove less useful.

A 3-year study in the Netherlands was undertaken to establish prospectively the effect of cycled prophylactic treatment of 3-monthly 3-week treatments with oral ciprofloxacin and inhaled colistin or placebo on prevention of initial *P. aeruginosa* infection in 65 children with CF. No difference was found in acquisition of *P. aeruginosa* infection between the control and treatment groups (annual incidence, 14% vs. 11%). Chronic infection was observed in 19 percent of controls and 12 percent of treated patients. Decline in pulmonary function and other clinical outcomes did not differ between the two groups. Anti-*Pseudomonas* antibodies emerged earlier in the control group, but this difference had disappeared after 3 years. In the treatment group, significantly fewer gram-positive bacteria but more non-*P. aeruginosa* nonfermentative gram-negative bacteria were isolated, suggesting caution and judicious use of antimicrobial agents. At present, no recommendation exists on use of anti-*Pseudomonas* prophylaxis in children with CF.[412]

Aerosolized recombinant human deoxyribonuclease (rhDNase I [Pulmozyme]) has been shown to increase pulmonary function and reduce exacerbations of respiratory symptoms in CF patients with moderate-to-severe reduction in pulmonary function. A study in Denmark analyzed whether aerosolized rhDNase could reduce the number of bacterial infections in the lower respiratory airways of CF patients without chronic pulmonary infection over 1 year. Overall, the number of positive cultures was significantly higher in the untreated group (82%) than the treated group (72%) The most striking difference was found for *S. aureus*, with a prevalence of 30 percent in the untreated group in contrast to 16 percent in the treated group. Whether the mechanism for decreased infection rate is from an anti-inflammatory affect, improved mucociliary clearance of sputum, or other unknown mechanism has not been elucidated.[138]

Early Eradication of *Staphylococcus aureus* and *Pseudomonas Aeruginosa*

An increasingly practiced therapeutic strategy is to use antibiotics to eradicate initial acquisition of *P. aeruginosa*

and prevent or delay chronic infection. This strategy was described first in Europe at the Danish Cystic Fibrosis Center.[136,191,395,416,425] The rationale for this approach is that antibiotics may be effective at eradicating initial infection and colonization with *P. aeruginosa* because the organism burden is low, organisms are largely susceptible, and a biofilm has not yet been established.

In some CF centers in Europe, colistin and ciprofloxacin are administered every 3 months after the initial isolation of *P. aeruginosa* has occurred.[136] In contrast to historic controls, patients treated with this approach had improved lung function, improved survival rates, decreased prevalence of *P. aeruginosa*, and increased resistance to the therapeutic regimen.[395] In Australia, investigators used intravenous antibiotics followed by ciprofloxacin or aerosolized agents and found that 6/24 children no longer had *P. aeruginosa* isolated for 12 months or longer.[14] In contrast to children treated with placebo, children treated with inhaled tobramycin within 7 to 12 weeks of initial infection and colonization with *P. aeruginosa* had shorter time to conversion from a positive to negative culture.[443] All 8 patients treated with inhaled tobramycin compared with 1/13 patients treated with placebo had successful eradication of *P. aeruginosa*.[148]

Despite the concerns about the potential emergence of antimicrobial resistance and lack of long-term studies that show the durability of eradication or an improvement in lung function, the growing consensus has been that early eradication for *P. aeruginosa* has merit. Two large, placebo-controlled studies have assessed the efficacy of different eradication regimens using different durations of tobramycin inhaled solution (TIS) with and without oral ciprofloxacin. Neither of these trials compared an active regimen with placebo—evidence that early eradication has been endorsed by CF experts. The EarLy Inhaled Tobramycin for Eradication (ELITE) study was designed to assess the efficacy and safety of two regimens (28 and 56 days) of TIS twice daily for treatment of early-onset *P. aeruginosa* infection in 88 children ages 6 months of age and older with CF. The median time to recurrence of *P. aeruginosa* (any strain) was similar between the two groups. In total, 93 and 92 percent of the patients were free of *P. aeruginosa* infection 1 month after the end of treatment and 66 and 69 percent remained free at the final visit in the 28-day and 56-day groups, respectively.[318]

A second study called Early Pseudomonas Infection Control (EPIC) was performed between 2004 and 2009 in 304 children, ages 1 to 12 years, within 6 months of first culture positivity to *P. aeruginosa*. This complex study randomized participants to one of four antibiotic regimens for 18 months (six 12-week quarters). Participants who were randomized to cycled therapy received TIS for 28 days, with oral ciprofloxacin or oral placebo for 14 days every quarter, and participants randomized to culture-based therapy received the same treatments only during quarters with positive *P. aeruginosa* cultures. There were no statistically significant differences in exacerbation rates between cycled and culture-based groups or ciprofloxacin and placebo. Treatment-emergent resistance to tobramycin or ciprofloxacin in *P. aeruginosa* was very infrequent (<1% of isolates).[413]

Despite wide use of oropharyngeal cultures to identify pulmonary infection, concerns remain over their diagnostic accuracy. The Australasian Cystic Fibrosis Bronchoalveolar Lavage (ACFBAL) randomized controlled trial recruited 170 infants diagnosed with cystic fibrosis through newborn screening programs in eight Australasian cystic fibrosis centers to study whether BAL-directed therapy for pulmonary exacerbations during the first 5 years of life provides better outcomes than current standard practice relying on clinical features and oropharyngeal cultures. The BAL-directed therapy group underwent BAL before 6 months of age when well; when hospitalized for pulmonary exacerbations, if *P. aeruginosa* was detected in oropharyngeal specimens; and after *P. aeruginosa* eradication therapy. Treatment was prescribed according to BAL or oropharyngeal culture results. The primary outcomes at 5 years of age were prevalence of *P. aeruginosa* on BAL cultures and total cystic fibrosis CT (CF-CT) score (as a percentage of the maximum score) on high-resolution chest CT scan. At 5 years of age, 8/79 children (10%) in the BAL-directed therapy group and 9/76 (12%) in the standard therapy group had *P. aeruginosa* in final BAL cultures. There was no difference in the mean total CF-CT score for the BAL-directed therapy and standard therapy groups (3.0% and 2.8%, respectively). In children with cystic fibrosis, BAL-obtained cultures did not offer any advantage in directing therapy nor result in a lower prevalence of *P. aeruginosa* infection or lower total CF-CT score in contrast to standard therapy at 5 years of age.[434]

Finally, patients with cystic fibrosis are becoming increasingly infected with MRSA as opposed to MSSA. There is some accumulating evidence that patients with MRSA show a more rapid deterioration in their degree of obstructive disease as measured by forced expiratory volume in 1 second (FEV_1) and that MRSA infection is independently associated with worse outcomes in cystic fibrosis.[80,92,157,364]

More longitudinal data are needed to understand how MRSA colonization and infection affect the course of disease in CF and whether eradication is possible. Currently few clinical data exist regarding approaches to MRSA eradication. Several investigators in Europe have published small case series of various regimens for eradication of MRSA that have included oral agents (e.g., rifampin and fusidic acid) and inhaled agents (e.g., vancomycin).[144,234,237,376] Randomized treatment trials must be performed to establish the safety and efficacy of these strategies.

Close microbiologic monitoring of airway cultures is recommended based on current evidence that oropharyngeal cultures remain the optimal screening method in infants and young children, with routine BAL-obtained cultures unnecessary. Early treatment to eradicate *P. aeruginosa* is a well-accepted treatment strategy, with strong evidence that a 28-day course of therapy of judicious use of tobramycin inhalation solution is recommended; addition of ciprofloxacin provides no benefit.

Treatment of Pulmonary Exacerbations

Pseudomonas aeruginosa

Much effort has been put into standardizing and validating the definition of a pulmonary exacerbation in CF. However, no currently accepted definition has been adopted universally for use clinically, in quality improvement initiatives, or in clinical research. A combination of clinical signs and symptoms is used to define a pulmonary exacerbation in research trials, and similar factors are used in the clinical setting.

Mild exacerbations often are treated with oral ciprofloxacin[64,176] with or without an inhaled agent such as aztreonam, tobramycin, or colistin. Treatment trials supporting the use of inhaled antibiotics for management of an exacerbation are lacking, however.

Several pivotal trials have led to widely accepted principles for intravenous treatment of more severe pulmonary exacerbations. During the 1970s and early 1980s, placebo-controlled trials showed that participants in the placebo group had increased morbidity and mortality rates in contrast to participants treated with intravenous antibiotics.[153,184,442] Hospitalized participants treated with bronchodilators and chest physiotherapy alone had less improvement in lung function and less reduction in bacterial density in contrast to patients treated with these interventions plus a β-lactam and an aminoglycoside agent.[321] Treatment with a β-lactam (azlocillin) and an aminoglycoside (tobramycin) agent leads to a significant reduction in bacterial density and a longer time to readmission for a new exacerbation in contrast to treatment with azlocillin alone.[369]

Studies also compared have various agents, singly or in combination. Most studies enrolled small numbers of patients and concluded that the comparative treatment regimens were equivalent in efficacy, but the studies were insufficiently powered to detect differences.* Many studies showed the emergence of resistance to study drug at the completion of therapy, which did not correlate with clinical response to treatment.[192,292] A larger multicenter trial randomly assigned patients undergoing a pulmonary exacerbation to ceftazidime and tobramycin (n = 52) or meropenem and tobramycin (n = 50).[28] Participants in the meropenem-treated group had a greater improvement in lung function than participants in the ceftazidime-treated group mean FEV_1 percent predicted (38.8% vs. 29.4%). An additional study in 118 patients in Germany compared ceftazidime and tobramycin to meropenem and tobramycin as treatment of a pulmonary exacerbation. Both treatment groups improved lung function measures and demonstrated reductions in bacterial sputum burden and acute phase reactant levels; no differences between treatment groups were observed.[222]

The advantage of alternative dosing schedules of time-dependent antimicrobials, by extended or continuous infusions, have theoretical advantages in the chronic treatment of *P. aeruginosa* in the CF airway. Certain antibiotics, such as β-lactams (i.e., penicillins, cephalosporins, carbapenems, and monobactams), clindamycin, macrolides (i.e., erythromycin and clarithromycin), and oxazolidinones (i.e., linezolid), can be effective because of the extensive amount of time the antibiotic binds to the microorganism. Few studies have been performed in the CF population to determine the safety and efficacy of extended or continuous infusion. A large multicenter, randomized cross-over study in France compared infusions of thrice-daily short infusions or daily continuous infusion of ceftazidime in 70 patients with CF and chronic *P. aeruginosa* infection; all patients were also treated with intravenous tobramycin. The primary end point was the variation in the FEV_1 during the course of antibiotic treatment. The improvement in FEV_1 at the end of therapy was not statistically different between the two treatment procedures (+7.6% after continuous infusion and +5.5% after short infusions) but was better after continuous ceftazidime treatment in patients harboring resistant isolates. The interval between the courses of antibiotic treatments was longer after the continuous infusion than after the short infusion of ceftazidime. The susceptibility profiles of the *P. aeruginosa* isolates remained unchanged and were similar for both regimens. Quality-of-life scores were similar whatever the treatment procedure, but 82 percent of the patients preferred the continuous-infusion regimen. Further studies are needed to demonstrate the safety and efficacy of continuous infusion of other antimicrobial agents.[182]

Finally, examination of the safety and efficacy of single daily dosing of tobramycin versus multiple daily dosing during a pulmonary exacerbation showed that single daily dosing was associated with the same efficacy and reduced nephrotoxicity; in children, the mean percentage change in creatinine in the single daily dosing group was less than the mean change in the thrice-daily dosing group (4.5% vs. 3.7%).[373]

Accepted treatment of a pulmonary exacerbation caused by *P. aeruginosa* consists of two parenteral agents from different antibiotic classes to provide synergy and delay the emergence of resistance.[147,266,313,349] Most commonly, a β-lactam agent with activity against *P. aeruginosa*, such as piperacillin or ceftazidime, is combined with an aminoglycoside agent, generally tobramycin. If a patient is coinfected with another pathogen, such as *S. aureus*, additional agents are added. Treatment trials for pulmonary exacerbations caused by other CF pathogens are unavailable, however.

Antibiotic dosages must be higher, more frequent, or both in patients with CF because the volume of distribution and clearance are increased in CF.[95] Treatment is administered for 10 to 21 days. Treatment outcomes include improved lung function; improved well-being, improved quality of life, or both; and a reduction in organism burden. Eradication of pathogens does not occur, however.[291] The Epidemiologic Study of Cystic Fibrosis analyzed the relationship between pulmonary function and treatment strategies for pulmonary exacerbations; centers with patients in the upper quartile of pulmonary function treated pulmonary exacerbations

*References 32, 89, 154, 189, 215, 252, 298, 354, 361.

more frequently than did centers in the lower quartile.[261]

Inevitably, *P. aeruginosa* develops increasing resistance to antibiotics. Molecular studies have confirmed that resistance generally develops in the infecting strains, rather than the acquisition of more resistant strains,[282] although superinfection with multidrug-resistant *P. aeruginosa* can occur as described subsequently.[245] Much interest has been generated in optimizing the treatment of pulmonary exacerbations caused by multidrug-resistant *P. aeruginosa* using in vitro synergy testing. Most commonly, checkerboard broth microdilution assays and multiple combination bactericidal testing have been studied.[221,349]

The activity of clinically achievable concentrations of pairs of antimicrobial agents with different mechanisms of action (e.g., a β-lactam agent paired with an aminoglycoside) have been tested.[349] To determine if a combination of agents is synergistic, a fractional inhibitory concentration can be calculated; synergy is defined as a fourfold reduction in the MIC of agents alone in contrast to agents in combination.[240] Most multidrug-resistant strains, defined as resistance to all agents in two or more classes of antibiotics,[343] can be inhibited by one or more combinations of agents, but the efficacy of this assay has not been validated in clinical trials. In contrast, a pivotal randomized trial to study the clinical efficacy of multiple combination bactericidal testing synergy studies was performed in Canada and Australian which patients undergoing a pulmonary exacerbation were randomly assigned to treatment guided by multiple significant differences in the time that elapsed until the next pulmonary exacerbation or improvements in lung function between the two treatment strategies were noted.

Recent studies using culture-independent molecular techniques, such as sequencing, high-throughput pyrosequencing, and phylogenetic microarray analysis, and anaerobic cultures have broadened our view of CF airway bacterial communities by comprehensively examining the airway microbiome in CF. The CF airway bacterial communities are highly complex, with anaerobes frequently present, and important evidence demonstrates that loss of community diversity and richness is associated with older age and decreased lung function in CF. Bacterial communities are also likely influenced by antibiotic use, chronic *P. aeruginosa* infection, host genetic background (del508F CFTR mutation), and geographic variations. Quantitative anaerobic cultures also detect high quantities of anaerobes from CF airway samples, including during pulmonary exacerbations. The effect of antimicrobial therapy on the airway microbiome needs further investigation. In addition, probiotic approaches have been recently studied; whether probiotics act by altering microbial communities or by modulating host inflammatory response is unknown. Complex bacterial communities, including traditional CF-associated pathogens and anaerobic bacteria, are common in CF airways. Novel therapeutic approaches aimed at modulating airway bacterial communities may lead to improved treatment of CF lung disease.[460]

Conventional antibiotic susceptibility often results correlate poorly with clinical outcomes in patients with CF. A multicenter randomized pilot trial was conducted to assess the efficacy and safety of using biofilm susceptibility testing *of P. aeruginosa* isolates to guide antibiotic regimens for chronic airway infections in clinically stable adolescent and adult CF patients. Thirty-nine participants were randomized to biofilm or conventional treatment groups; 14-day courses of two antibiotics were selected according to an activity-based algorithm using the corresponding susceptibility results. Meropenem was most active against biofilm-grown bacteria and was included in regimens for about half of each study group. Microbiologic and clinical responses in patients with biofilm testing did not differ significantly from patient regimens based on conventional testing. The predictive value of biofilm testing may nonetheless warrant evaluation in an adequately powered clinical trial in younger CF patients or those experiencing acute pulmonary exacerbation.[264]

CF experts have not arrived yet at a consensus regarding the efficacy of inpatient versus outpatient management of pulmonary exacerbations. Outpatient management has advantages; it is less costly, is less disruptive to patients and their families, and involves less risk for acquiring nosocomial pathogens. Patients treated at home were shown, however, to have longer treatment courses and less improvement in lung function.[273] Patients may improve more with hospitalization, as a result of better compliance with antibiotics, bed rest, chest physiotherapy, and bronchodilator treatments.[34]

Staphylococcus aureus *and Methicillin-Resistant* Staphylococcus aureus

The clinical utility of antistaphyloccocal agents is best shown by early studies of infants with CF treated with penicillin before the nearly universal acquisition of β-lactamases by *S. aureus*.[9,253] Infants treated during the antibiotic era had markedly improved survival rates. Experts advocate the use of a first-generation cephalosporin (e.g., cephazolin) or a semisynthetic penicillin (e.g., oxacillin) for treatment of a pulmonary exacerbation associated with MSSA.[147] Treatment trials justifying this approach are lacking, however.

Vancomycin generally is advocated for treatment of MRSA when this organism is considered a pathogen. Although no treatment trials in CF patients using other anti-MRSA antimicrobial agents (i.e., clindamycin, trimethoprim-cotrimoxazole, rifampin, or linezolid) have been conducted, a case series showed that adults with CF required 600 mg of linezolid every 8 hours to provide desired pharmacokinetics.[33,353] Linezolid-resistant MRSA did emerge in a child with CF treated for approximately 3 months.[140] A small study of eight adults with CF was randomized to receive intravenous and oral linezolid for nine doses in a cross-over design with a 9-day washout. Population pharmacokinetic analyses were performed, and at the steady state, the twice-daily dose produced 93.0 and 87.2 percent probabilities of obtaining the target pharmacodynamic exposure against the MRSA isolates for the intravenous and oral formulations, respectively. Thrice-daily dosing increased the probabilities to 97.0 and 95.6 percent, respectively. This study concluded that

standard intravenous and oral dosing regimens should be sufficient to reliably attain pharmacodynamic targets against most MRSA isolates; however, more frequent dosing may be required for isolates with MICs of 2 μg/mL or greater.[199]

Because linezolid is available orally and intravenously, the potential for "abuse" exists if clinicians do not use this agent judiciously.

Burkholderia cepacia *Complex*

Management of *B. cepacia* complex is more problematic because of higher levels of intrinsic antibiotic resistance and a paucity of clinical trials for this pathogen. Initial isolates may be susceptible to ciprofloxacin, β-lactam antibiotics, chloramphenicol, trimethoprim-sulfamethoxazole, meropenem, and minocycline, but with the exception of *Burkholderia gladioli*, all *Burkholderia* spp. are resistant to aminoglycosides. Temocillin has been used in Europe to treat pulmonary exacerbation caused by *B. cepacia*.[406] Resistance can develop, however, which severely limits therapeutic options. As described for the management of *P. aeruginosa*, combinations of two or three agents are used to treat a pulmonary exacerbation. Even more prolonged courses may be required to improve lung function. Meropenem and minocycline were noted to have the most in vitro activity against 652 multidrug-resistant *Burkholderia* strains isolated from patients with CF and inhibited 28 percent and 33 percent of strains.[232] Treatment may be guided by two or more drug combinations with an evident improvement in pulmonary function.[1,465]

Stenotrophomonas maltophilia *and* Achromobacter xylosoxidans

No published treatment trials have been conducted for patients with CF who are harboring *S. maltophilia* or *A. xylosoxidans* and are undergoing an exacerbation. Although definitive data confirming that these organisms are pathogens in CF are unavailable, clinicians target these multidrug-resistant, gram-negative bacilli if they are consistently recovered from the respiratory tract of an individual patient. At present, the Clinical Laboratory Standards Institute recommends testing ticarcillin-clavulanate, ceftazidime, minocycline, chloramphenicol, trimethoprim-sulfamethoxazole, and levofloxacin against *S. maltophilia*,[67] but CF strains frequently are resistant to these agents.[352]

Nonetheless, similar strategies are used to treat these organisms as described for *P. aeruginosa* or *B. cepacia* complex; two or more parenteral agents are chosen based on susceptibility testing and given for 2 to 3 weeks. In a survey of 263 isolates of *S. maltophilia* from 218 patients with CF isolated from 1995 to 1998, doxycycline, ticarcillin-clavulanate, piperacillin-tazobactam, and trimethoprim-sulfamethoxazole were most active and inhibited 78 percent, 39 percent, 18 percent, and 13 percent of isolates, respectively.[352,465] A survey of 94 *A. xylosoxidans* isolates from 77 patients showed that meropenem and imipenem, or piperacillin with or without tazobactam, were most active.[347]

Nontuberculous Mycobacteria

Treatment of NTM in patients with CF is challenging and guided by the clinical presentation and the mycobacterial species. Before therapy for NTM is initiated, patients should be treated aggressively for the classic CF pathogens they harbor to determine if they clinically improve without the need for specific NTM treatment. If NTM treatment is initiated, a careful history, physical examination, and pulmonary function tests should be done to determine the baseline status of the patient in efforts to monitor response to therapy. Susceptibility testing for NTM is not done routinely for patients who do not have CF. Given the increased antibiotic exposure in CF and the potential for the emergence of resistance, NTM strains isolated from patients with CF should undergo susceptibility testing at a reference laboratory. Treatment can be guided by the initial susceptibility profile.

No treatment trials have been published for NTM in CF, and generally regimens are comparable to those used in patients without CF. Treatment of MAC is straightforward and includes a macrolide agent, rifabutin, and ethambutol. Treatment of *M. abscessus* is more complex. Many experts have a lower threshold for treating *M. abscessus*, given the greater apparent virulence of this species in CF, including after lung transplant.[59] Some experts recommend oral therapy, including a macrolide and linezolid because both have excellent in vitro activity, for stable patients.[40] Some experts add vitamin B_6 to prevent peripheral neuropathy, but the pathogenesis of peripheral neuropathy from linezolid is unknown. For more symptomatic patients, intravenous therapy, including cefoxitin or a carbapenem, depending on susceptibilities and amikacin, is recommended. Such patients need to have their hearing assessed regularly. Because of the potential for different pharmacokinetic properties in CF and the fact that oral agents may not be well absorbed by patients with CF, serum levels for antimycobacterial agents should be strongly considered.[151,301]

Patients should be followed closely and have monthly sputum testing done for acid-fast bacillus smear and culture. The response to treatment generally is good for patients infected with MAC. Although the optimal duration of treatment has not been studied, experts recommend continuing therapy for 1 year after negative sputum cultures have been obtained. Cure for *M. abscessus* is less likely to occur, and the therapeutic goal may be long-term suppression. After clinical and mycobacterial improvement (i.e., a reduction in organism burden) has been achieved, intravenous antibiotics can be stopped and prolonged oral therapy with a macrolide can be initiated.

Allergic Bronchopulmonary Aspergillosis

Treatment of ABPA also can be very challenging. Although steroids are the treatment of choice because ABPA is immunologically mediated, the response to steroids varies and may have the undesirable consequence of diabetes in this vulnerable patient population. The oral antifungal therapies voriconazole[174] and itraconazole[274]

have been used with reported response and toxicity, but no controlled trials have been performed.[266] Monitoring serum levels of itraconazole is desirable because this agent may be malabsorbed if the gastric pH is nonacidic.

Long-Term Suppressive Therapy

Inhaled Antibiotics. Long-term suppressive antibiotic therapy has been used increasingly to treat patients with CF and infected with *P. aeruginosa* to prolong the time between pulmonary exacerbations and slow the progression of lung deterioration. Numerous oral agents that are not cidal for *P. aeruginosa* (e.g., amoxicillin-clavulanate, trimethoprim-sulfamethoxazole, or tetracycline agents) are used empirically, sometimes in rotation, with anecdotal support coming from patients and physicians. The use of oral antibiotics is widespread; during a 6-month period, 90 percent of patients received at least one course of oral antibiotics.[46] No clinical trials support this practice, however, and it may contribute to antibiotic resistance.

For decades, inhaled agents such as tobramycin, colistin, gentamicin, amikacin, and various β-lactam antibiotics, including carbenicillin and cephaloridine, also have been used for management of chronic infections.[48] Definitive data supporting the use of inhaled agents were derived from a multicenter phase III, double-blind, placebo-controlled, randomized treatment trial of inhaled tobramycin (TOBI) in patients with CF and chronic *P. aeruginosa* infection.[315] Patients received 300 mg of tobramycin twice daily every other month for 6 months. The rationale for administering therapy every other month was to delay the emergence of resistance, to reduce cost, to increase compliance, and potentially to exploit the postantibiotic effect of aminoglycosides. Subjects randomly assigned to inhaled tobramycin had a 10 percent improvement in FEV_1 in contrast to subjects who received placebo, who experienced a 2 percent decline in FEV_1. Treated patients also had a reduction in bacterial density, fewer days of hospitalization, and fewer days of intravenous antibiotics. In subset analyses, adolescents had the greatest improvement in pulmonary function. During treatment, patients receiving tobramycin had increased tinnitus that was unassociated with hearing loss. Minimal systemic absorption of tobramycin occurred because serum levels of tobramycin generally were less than 1 μg/mL.

Although this study confirmed the efficacy of inhaled tobramycin in CF patients with chronic *P. aeruginosa* infection, several questions remain. In routine antimicrobial susceptibility testing, the breakpoint for resistance to tobramycin is MIC of 16 μg/mL or greater. The aerosol route delivers 100-fold higher concentrations of tobramycin without toxicity, however; the median concentration of tobramycin in the phase III trial was 1200 μg/g of sputum.[315] Although the conventional breakpoint for resistance to tobramycin is irrelevant for drug delivered by inhalation, the breakpoint for inhaled tobramycin is unknown. Commercially available susceptibility tests do not measure MICs greater than 8 μg/milk During the 6-month trial, resistance to tobramycin did occur; a trend was found toward higher MICs in the treatment group (median MIC, 2 μg/mL) in contrast to the placebo group (median MIC, 1 μg/mL). The same laboratory studied the prevalence of *P.* aeruginosa antibiotic resistance in 2008 and evaluated whether the prevalence of other CF pathogens has changed. In the decade since TIS licensure, antibiotic usage in the care of patients in CF has changed. The study recruited a contemporary cohort of CF patients meeting similar eligibility criteria as the 520 patients in the phase III trial of inhaled tobramycin (historical cohort). Sputum samples from 33 U.S. CF centers with a total of 656 *P. aeruginosa* isolates were identified from 253 culture-positive patients. Comparison between cohorts revealed an increase in the prevalence of patients with tobramycin-resistant (11.8% vs. 30.4%, $p < .001$) and amikacin-resistant (24.2% vs. 42.7%, $p < .001$) *P. aeruginosa* between 1995 and 2008. Prevalence of ciprofloxacin resistance was similar (34.4% vs. 33.6%, $p = .81$). Within the contemporary cohort, potential associations between recent antibiotic exposures and prevalence of *P. aeruginosa* resistance were examined; findings included that exposure to intravenous carbapenems was significantly associated with aztreonam resistance, meropenem resistance, and multidrug resistance ($p = .0002$, $p = .0003$, and $p = .0002$, respectively). Prevalence of *S aureus*, MRSA, *S maltophilia*, and *A xylosoxidans* was also increased in the contemporary cohort.[119]

Buoyed by the success of aerosolized tobramycin, other aerosolized agents have been developed. The effectiveness and safety of aztreonam lysine for inhalation in patients with CF on maintenance treatment for chronic *P. aeruginosa* airway infection and moderate-to-severe lung disease was evaluated in two 28-day treatment multicenter phase III, double-blind, placebo-controlled, randomized treatment trials. The 28-day treatments with aztreonam lysine significantly delayed need for inhaled or intravenous antipseudomonal antibiotics, improved respiratory symptoms and pulmonary function, and was well tolerated.[249,324] A third study was an international 18-month, open-label study that evaluated the safety and efficacy of repeated courses of aztreonam lysine for inhalation solution in patients with chronic *P. aeruginosa* infection and moderate-to-severe lung disease. With each course of aztreonam lysine, FEV_1 and scores on the Cystic Fibrosis Questionnaire–Revised Respiratory Symptom scale improved and bacterial density in sputum was reduced. In the 28 days off therapy, benefits waned, but weight gain was sustained over the 18 months. There were no sustained decreases in *P. aeruginosa* susceptibility. A dose response was observed; aztreonam lysine in patients treated thrice daily demonstrated greater improvements in lung function and respiratory symptoms. Clinical benefits in pulmonary function, health-related quality of life, and weight were observed with each course of therapy.[281]

An additional double-blind, multicenter, randomized, placebo-controlled trial of aztreonam lysine enrolled 157 patients with CF with chronic *P. aeruginosa* infection who had mild lung disease. Treatment effects favoring aztreonam lysine were larger for patients with baseline FEV_1 less than 90 percent of predicted in contrast to 90 percent

or greater of predicted. Aztreonam lysine was well-tolerated. The effects on respiratory symptoms were modest; however, FEV_1 improvements and bacterial density reductions support a possible role for aztreonam lysine in these relatively healthy patients.[433]

In 2010, aerosolized aztreonam lysine (now marketed as Cayston) was approved for long-term intermittent, 28 days on and 28 days off, suppressive therapy in patients with moderate-to-severe lung disease, with a dose of 75 mg three times per day. Aztreonam lysine is delivered via the Altera nebulizer system, a proprietary eFlow nebulizer device optimized with a short (<3 minutes) delivery time.

Many controversies surround inhaled antibiotics and include whether there is a role or benefit for (1) aerosolized antibiotics in the treatment of a pulmonary exacerbation with chronic *P. aeruginosa*, (2) continuous alternating therapy, (3) treatment of non-*Pseudomonas* chronic infection, or (4) alternative dosing regimens (e.g., 2 weeks on and 2 weeks off regimen, use of multiple inhaled antibiotics within the same month). A clinical trial comparing continuous-alternating therapy of aztreonam and TIS versus tobramycin as a 28 days on and 28 day off suppressive therapy, is currently underway. Recognizing that new treatment options for CF pulmonary infections are needed has led to the development and study of additional inhaled antimicrobials agents for suppressive therapy, which include inhaled levofloxacin,[145] dry powder ciprofloxacin, tobramycin inhalation powder, and amikacin. Aztreonam lysinate and amikacin for inhalation delivered via liposome formulations are being studied as a way to penetrate mucoid biofilms and prolong the residence time of the antibiotic in the lungs. Light, porous, dry-powder formulations are also in clinical trials to reduce delivery time. These new formulations and delivery systems promise to expand our armamentarium against microbes while reducing the time burden for patients. Guidelines and further studies are needed to guide their optimal and judicious use.

Macrolide Antibiotics. Much interest has been generated more recently in the use of macrolide agents in CF[180] as long-term suppressive therapy. The rationale for macrolide therapy in CF stems from the successful treatment of diffuse panbronchiolitis with erythromycin, azithromycin, and clarithromycin.[207,216] Diffuse panbronchiolitis is a chronic lung disease, diagnosed primarily in Asian adults, with several clinical features similar to those found in CF, including progressive lung disease caused by mucoid and nonmucoid strains of *P. aeruginosa*.[392] Long-term administration of low-dose macrolide agents to patients with diffuse panbronchiolitis has reduced morbidity and mortality rates.

In vitro studies have provided the scientific rationale for this clinical efficacy. Although macrolides are not cidal for *P. aeruginosa*, subinhibitory concentrations of macrolide agents reduce the production of several virulence factors by *P. aeruginosa*,[257,258] including the formation of biofilm.[187,209] Macrolide antibiotics also may have an anti-inflammatory effect and decrease cytokine production by neutrophils, monocytes, and bronchial epithelial cells.[186,456]

Six azithromycin trials have been conducted in patients with CF so far.*

Four trials were conducted in patients chronically infected with *P. aeruginosa*[122,195,346,449] and had similar results; all showed improvement in lung function using similar treatment regimens of azithromycin. Improvements in secondary outcomes, such as decreased hospitalization, decreased antibiotic use, and increased weight gain, also were noted. In a large study performed in 260 children and adolescents, with negative cultures for *P. aeruginosa*, pulmonary exacerbations occurred in 21 percent of the azithromycin group and 39 percent of the placebo group. Participants in the azithromycin group had a 50 percent reduction in exacerbations and an increase in body weight in contrast to placebo participants. Treatment with azithromycin for 24 weeks did not result in improved pulmonary function.[344] Cochrane review of azithromycin use in patients with CF provides evidence of improved respiratory function after 6 months of treatment. Data beyond 6 months were less clear, although reduction in pulmonary exacerbation was sustained and the studies concluded that short-term (i.e., 6 months) azithromycin seemed effective in CF, but long-term safety and efficacy remain unknown.[378,379] Patients treated with azithromycin should be screened for NTM before initiating therapy and annually thereafter because of concern about macrolide resistance in these microorganisms.

Lung Transplantation

Lung transplantation currently is considered a viable therapy for selected patients with end-stage pulmonary disease of CF.[457] Bilateral lung, heart and lung, and living donor lobar lung transplantation all have been performed in patients with CF, but most operations in recent years have used the bilateral lung transplant approach with lungs from deceased donors. By 2012, more than 3000 individuals with CF had undergone lung transplantation worldwide, with nearly 150 to 200 procedures performed annually as of 2012. The survival of lung transplant recipients with CF exceeds that of any other diagnostic group for all ages, with projected survival half-life of 6.2 years.[414] Patients with CF nonetheless present special challenges for successful lung transplantation, complicated by other comorbidities such as CF-related diabetes, gastroesophageal reflux, CF liver disease, and bone metabolism. The life-threatening manifestations of CF generally are limited to the lungs, except for patients with advanced liver disease with portal hypertension.[39] Advantages of a lung transplant recipient with CF include relative young age, giving the potential of many years of productive life ahead. In addition, patients with CF have experience with complex medical regimens.

The optimal time to refer potential candidates for evaluation for lung transplant is difficult to determine because the natural history of CF cannot be predicted precisely. In May 2005 in the United States, the United Network for Organ Sharing introduced a new system of

*References 66, 122, 195, 344, 348, 449.

lung distribution that assigns a lung allocation score to each potential candidate. Key parameters used in the lung allocation score include lung function testing, the need for oxygenation, the presence of diabetes mellitus, age, body mass index, the need for ventilatory support, hospitalization in the intensive care unit, and hemodynamic data from cardiac catheterization. Waiting time is usually not considered except in individuals younger than 12 years of age. There are no microbiologic criteria.[115]

Although transplanted lungs do not develop CF, they can become infected with the pretransplant pathogens because the trachea and paranasal sinuses continue to manifest the pathophysiology of CF. Lung transplant recipients with CF are at risk for development of infection via pretransplant microbial flora or newly acquired pathogens.[197,230,375,386] Controversy has ensued about whether microbiologic criteria, specifically pretransplant infection with fungi, NTM, or multidrug-resistant pathogens, should be considered contraindications to performing lung transplantation in patients with CF. Several centers have published their experiences with infections that developed from lung transplantation pathogens; they include invasive aspergillosis; sepsis with *S. maltophilia*, *B. cepacia* complex organisms, and *B. gladioli;* and sternal wound infection.[197] Other centers have reported that morbidity and mortality caused by *P. aeruginosa* infections after transplant are not higher in patients with CF than in patients who do not have CF.[135,278]

A more recent study indicated that lung transplant recipients with CF and with panresistant, gram-negative organisms other than *Burkholderia* spp. had significantly decreased survival rates after transplantation than a comparable group with antibiotic-sensitive organisms.[167] Patients with CF who are infected with *B. cenocepacia* have increased morbidity and mortality rates from recurrent infection, sepsis, or both after lung transplantation. Although Aris and colleagues[11] did not detect patient-to-patient transmission, increased mortality rates were noted with *B. cenocepacia* but not with multidrug-resistant *P. aeruginosa*. Patients infected with genomovar III had increased mortality rates after lung transplantation in contrast to patients infected with other genomovars before transplantation.[11]

Infection with *M. abscessus* before undergoing transplant can be associated with severe posttransplant complications and death.[62,405] Acquisition of NTM after transplant can be treated successfully with prolonged combination of antimicrobial therapy.[62,239] Patients with CF are at risk for developing invasive aspergillosis after transplant, but at lower rates than patients without CF.[278,295] Many of these patients with CF were colonized with *Aspergillus* spp. before undergoing transplantation. Treatment with antifungal therapy after surgery should be considered. The U.S. Cystic Fibrosis Foundation held a consensus conference on lung transplantation in 1996.[457] The conferees concluded that microbiologic contraindications to transplantation were limited to active hepatitis B and human immunodeficiency virus. The decision to perform transplants patients infected with *B. cepacia* complex or multidrug-resistant *P. aeruginosa* or colonized with *Aspergillus* spp., should be made on a case-by-case basis. Potentially, an understanding of the genomovar infecting a patient may be a useful predictor of mortality.

Anti-Inflammatory Therapy

Inflammation associated with chronic bacterial colonization plays a crucial role in CF lung disease. Nonsteroidal agents and glucocorticoids have been used as potential medications for anti-inflammatory therapy. A randomized trial using oral prednisone 1 to 2 mg/kg every other day showed a reduction in the rate of decline in pulmonary function of patients with CF but was associated with significant steroid-related side effects.[17] Three short-term trials using inhaled steroids have led to mixed results and no clear direction for long-term use.[18,276,421]A systematic review of inhaled steroids for CF was equivocal with respect to efficacy.[100] A multicenter randomized trial of withdrawal of inhaled steroids in CF did not find a difference in pulmonary exacerbations, infection with *P. aeruginosa*, or pulmonary function after inhaled steroids were discontinued.[19] A pilot study in of 24 patients with CF being treated with antimicrobial standard therapy for a pulmonary exacerbation were randomized to receive oral prednisone 2 mg/kg/day up to 60 mg or placebo on days 1 to 5. Study evaluations on days 1 to 6, 14, and 42 included spirometry, glucose measurements, sputum analysis, and symptom scores. Mean increase in FEV_1 percentage of predicted did not differ significantly between prednisone and placebo groups, with a trend toward improvement in pulmonary function with the prednisone therapy group; sputum inflammatory markers and symptom scores did not differ between groups. Glucosuria occurred in six prednisone subjects, two of whom developed hyperglycemia. Based on these results, a definitive study of a much larger group of subjects is required to detect a treatment effect before routine recommendation of steroid use can be made.[107] High-dose ibuprofen 20 to 30 mg/kg twice daily used over a 4-year period showed a decreased rate of decline in pulmonary function with few reported side effects.[211] Macrolide antibiotics decrease inflammation by modulation of inflammatory signaling pathways and decreased cytokine production from inflammatory cells.[118] Several anti-inflammatory agents, including antiproteases, statins, and antioxidants, have been proposed as potential therapies, but they remain under investigation and are not a part of routine clinical practice.

PREVENTION

Immunizations

The use of currently available routine childhood and adolescent vaccines is strongly advocated for patients with CF. Although patients with CF are not at increased risk for developing *S. pneumoniae* infections, they should receive the pneumococcal 13-valent conjugate vaccine. Annual influenza vaccination is recommended for patients with CF and household members.[126,132] The RSV subunit vaccine PFP-2 (purified fusion protein vaccine is a fusion glycoprotein that induces serum neutralizing antibodies)

TABLE 25-5 **Risk Factors Associated with Acquisition of *Burkholderia cepacia* Complex**

Risk Factors	Comment
Attendance at CF summer camp[299]	Risk for acquisition (6% incidence) increased with time spent at camp and prevalence of *B. cepacia* at the camp
Slept in same cabin	
Shared a personal item	
Danced with *B. cepacia*–infected camper	
Attendance at summer educational program[229]	3 (20%)/15 patients acquired same ribotype
Participation in adult CF group	Disband meetings thought to represent extensive social contact
Social contact[159]	
Kissing	
Intimate contact	
Prolonged car rides	
Sibling with *B. cepacia* complex	
Handshaking	2/68 cultures positive, 1 from patient and 1 from investigator[300]
	3 patients' hands became contaminated after coughing[159]
Inpatient exposures	Risk for acquisition increased if hospitalized within 3 mo and if hospitalized longer
Recent hospitalization[300]	Interviews with health care workers indicated poor adherence to contact precautions
Use of specific shower	
Sharing hospital room with another patient infected with *B. cepacia*	
Cared for by a medical student	
Respiratory therapy equipment	Reservoirs of large-volume nebulizers grew *B. cepacia*
Sharing equipment	
Hospital nebulizers	
Spirometer[188]	
Mouthpiece filters[159]	

CF, Cystic fibrosis.

has been studied in children with CF for two RSV seasons.[306] Initial studies showed that the RSV subunit vaccine was safe and immunogenic and that it reduced the incidence of lower respiratory tract infections.[305] A large multicenter trial in patients with mild disease failed to show a reduction in the incidence of lower respiratory tract infection, however.[304] A placebo-controlled trial of RSV monoclonal antibody (palivizumab) was performed in 186 children.[380] Although palivizumab was well tolerated, two children were hospitalized (one in each group); the study was not adequately powered for efficacy. Consideration should be made for palivizumab use in infants with CF.

The results of a phase III multicenter study of a *P. aeruginosa* vaccine showed that a bivalent, antiflagella vaccine was immunogenic and was found to reduce the incidence of *P. aeruginosa* infection and serum antibody titers. It did not prevent chronic *P. aeruginosa* infection and did not affect lung function.[105] Current studies are ongoing evaluating the safety and effectiveness of a PEGylated, recombinant Anti–*P. aeruginosa* PcrV Fab' antibody targeted for use in patients with chronic *P. aeruginosa* infection.

Infection Control Precautions

Although the sources of most pathogens in patients with CF are unknown, it is increasingly recognized that patient-to-patient spread and acquisition from the contaminated health care environment can occur. To date, reports of transmission of bacterial pathogens occurring between individuals with and without CF are rare.[152,178,246] Direct contact, indirect contact, and spread of droplets with infectious secretions all have been implicated as modes of transmission of CF pathogens. Risk factors for transmission were described first for *B. cepacia* complex, as shown in Table 25-5.*

Perhaps of most concern have been several reports of clonal spread of *P. aeruginosa* among patients with CF.[245,359,360,418] These examples have involved obvious phenotypes that triggered an investigation of possible patient-to-patient spread, including an increase in ceftazidime-resistant *P. aeruginosa*[60] or initial colonization of young children with mucoid strains of *P. aeruginosa*.[14,277] These reports have led CF centers in Europe to favor cohorting and segregating patients with *P. aeruginosa*, particularly patients with antibiotic-resistant strains, in hospital and clinic settings.[136,208,245] In the United States, infection control strategies have focused on containment of respiratory tract secretions as described subsequently.[350] Finally, occasional cases of patient-to-patient spread of other potential pathogens, including *S. maltophilia* and *A. xylosoxidans*, have been reported in patients with CF.[329,417]

The U.S. Cystic Fibrosis Foundation convened an expert panel to develop revised recommendations for infection control that addressed inpatient, outpatient (i.e., CF clinic and pulmonary function test laboratories),

TABLE 25-6 **Infection Control Strategies for Cystic Fibrosis**

Guideline	Setting		
	Inpatient	Outpatient	Non–Health Care
Quarterly cultures of respiratory tract	X		
Appropriate processing of CF respiratory tract cultures	X	X	
Educate patients and families about proper hand hygiene	X	X	X
Implement contact precautions for MDROs, including MRSA	X	X	
Hospitalize patients with MDROs in single-patient room	X	X	
Segregate patients with *B. cepacia* complex from other CF patients	X	X	X
Clean and disinfect respiratory therapy equipment	X	X	X
Avoid socialization among CF patients	X	X	X
Maintain at least 3 ft between CF patients to prevent droplet transmission	X	X	X

CF, Cystic fibrosis; *MDROs,* multidrug-resistant organisms; *MRSA,* methicillin-resistant *Staphylococcus aureus.*

and non–health care settings, because so much CF care is delivered in the home. These recommendations have implications for treatment, transplantation, and the psychosocial well-being of patients, families, and staff. Several strategies are emphasized (Table 25-6). The guidelines emphasize that all patients with CF could harbor potentially transmissible respiratory tract pathogens, and containing respiratory tract secretions is of paramount importance.

The consensus is that patients harboring *B. cepacia* complex should be cared for apart from other patients with CF and not grouped together because of concern that some strains of *B. cepacia* complex may be more virulent and replace other strains.[236] Patients are hospitalized in single rooms and seen in outpatient settings geographically or temporally apart from other patients with CF. Similarly, patients with CF and MRSA in the respiratory tract should be placed in private rooms without access to common areas.

CONCLUSION

The microbiology of patients with CF is complex and changing. Although the pathogenesis of lung infections is still under active investigation, the current hypothesis suggests multiple etiologies. Appropriate microbiologic processing of respiratory tract specimens is crucial to ensure an accurate understanding of the epidemiology of CF lung disease and provide appropriate treatment and infection control. Current treatment strategies are directed largely at management of deteriorations of pulmonary function, but increasingly strategies are directed at prevention and preservation of lung function.

SECTION **III**

INFECTIONS OF THE HEART

CHAPTER 26

Infective Endocarditis

Jeffrey R. Starke

Infective endocarditis results when microorganisms adhere to the endocardial surface of the heart. This process usually occurs on heart valves, although septal defects and mural surfaces can be affected. Most episodes of endocarditis begin on endocardium that has been altered by congenital defects, previous disease, surgery, or trauma. The clinical manifestations depend on the degree of compromise of cardiac function and the occurrence of embolic phenomena. Although bacteria are responsible for most cases, instances of infective endocarditis caused by fungi, chlamydiae, rickettsiae, and perhaps viruses have been described. Advances in the practice of general pediatrics and cardiology during the past 3 decades have contributed to changes in the predisposing conditions and etiologic agents of infective endocarditis. Before the 1950s, rheumatic fever was the major underlying condition, but its incidence has declined greatly since then.[331] Improvements in the medical and surgical management of children with congenital heart disease have increased survival rates. Eighty to 90 percent of children with infective endocarditis have congenital heart disease. Many cases occur after cardiac surgery, especially for replacement of valves and creation of shunts with prosthetic materials.[367] The reported incidence of infective endocarditis in neonates is increasing, probably owing to the use of sophisticated and highly invasive techniques in neonatal intensive care nurseries.[98,172,354,435]

Infective endocarditis has been classified as acute or subacute, based on the progression of untreated disease.[474] The acute form has a fulminant course, with high fever, systemic toxicity, and death from sepsis in several days to 6 weeks. The most common etiologic agents are *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*. Children with the acute form often have no underlying cardiac lesion. Subacute disease usually occurs in patients with previous valvular disease or those who have undergone cardiac surgical intervention.[62] It is characterized by a more indolent course (6 weeks to several months) and with low-grade fever, vague systemic complaints, and various embolic phenomena. Viridans streptococci are the most common etiologic agents. This classification ignores the frequent overlap in clinical manifestations caused by various organisms, especially the staphylococci and fungi, which are causes of an increasing number of subacute cases in the postcardiac surgical setting. Classification based on specific etiologic agents is preferable because it has implications for the usual clinical course, predisposing factors, and appropriate medical and surgical management.[22]

EPIDEMIOLOGY

The incidence of infective endocarditis in adults has been difficult to determine because the methods of study and criteria for diagnosis vary among series.[33,131,381] Accurate figures on the incidence of infective endocarditis in children are difficult to obtain. The most common method of reporting the incidence in pediatric series expresses the number of cases of infective endocarditis as the numerator and the total number of hospital admissions during the analyzed period as the denominator. Zakrzewski and Keith[589] reported an incidence of endocarditis of 1 in 4500 pediatric admissions at the Hospital for Sick Children in Toronto from 1952 to 1962, whereas Van Hare and colleagues[553] at Case Western Reserve in Cleveland, Ohio, found an incidence of 1 in 1280 in the period from 1972 to 1982. In a large series from Boston Children's Hospital spanning the period between 1933 and 1972, the incidence before 1963 was 1 in 4500 pediatric admissions, whereas that for 1963 to 1972 was 1 in 1800 admissions.[248] A study from a children's hospital in Australia reported an incidence of 1 in 4500 hospital admissions between 1971 and 1983.[490] More recently, one Japanese center reported an annual incidence of 0.9 cases per 1000 children seen at the cardiology clinic.[169] Although differences in referral patterns at these centers may have introduced bias into these figures, the incidence of infective endocarditis in children appears to be rising. This rise may be explained by the increased survival rate of children with all forms of cardiovascular disease and an increase in the percentage of cases that occur after cardiac surgery[29] (especially implantation of foreign material[564]) and are related to intravascular catheters.[153,256,461] Early surgical correction of many types of congenital heart disease along with effective perioperative antibiotic prophylaxis regimens ultimately may lower the incidence of postoperative infective endocarditis. However, the increasing use of invasive therapeutic modalities, especially intravenous catheters and pacemakers, may lead to an increased incidence of health care–associated endocarditis.[153,159,338,436,565] In general, children with predisposing cardiac conditions who develop infective endocarditis while hospitalized have longer hospitalizations and higher mortality than patients with community-associated endocarditis.[335]

The average age of children with infective endocarditis is increasing, a phenomenon that may reflect the longer life expectancy created by improved therapy for

TABLE 26-1 **Underlying Heart Disease in 266 Children with Infective Endocarditis**

Underlying Heart Disease	Percentage Affected (%)
Congenital heart disease	78
Tetralogy of Fallot	24
Ventricular septal defect	16
Congenital aortic stenosis	8
Patent ductus arteriosus	7
Transposition of great vessel	4
Others	19
Rheumatic heart disease	14
No heart disease	8

From Kaplan EL. Infective endocarditis in the pediatric age group: an overview. In: Kaplan EL, Taranta AV, editors. *Infective endocarditis: an American Heart Association symposium.* Dallas: American Heart Association; 1977, p. 51–4.

children at risk.[521] From 1930 to 1950, the mean age for children with infective endocarditis was close to 5 years.[248] Between 1960 and the present, it increased to 8.5 and then to 13 years.[169,180,284,337,461] The number of reports of infective endocarditis in children younger than 2 years of age had been small but has increased significantly since the late 1980s.[43,180,354,573] The clinical course of infective endocarditis in these young children often is atypical, and some cases are diagnosed at autopsy.[248,409] Before the 1950s, this disease was a rare event in neonates, with only eight autopsy cases reported.[321] Several reports suggest a rapidly increasing rate associated with the development of intensive supportive care in neonates.* Symchych and colleagues[519] found a 3 percent incidence of bacterial endocarditis among all neonatal autopsies. Endocarditis in neonates frequently occurs on the tricuspid valve when associated with an indwelling central venous catheter.[539] Congenital heart defects also predispose neonates to the development of infectious endocarditis.[98]

Any form of structural cardiac disease may predispose to infective endocarditis, especially disorders associated with turbulence of blood flow.[176,498] In autopsy and clinical series, children with ventricular septal defect, tetralogy of Fallot, left-sided valvular disease, and systemic-pulmonary arterial communication were at highest risk, whereas those with pulmonary stenosis, coarctation of the aorta, and secundum atrial septal defect were at low risk.[451,461] Hypertrophic obstructive cardiomyopathy rarely is associated with infective endocarditis.[81] Isolated pulmonic or tricuspid valve endocarditis can occur in "otherwise normal" children and adolescents with sepsis or focal bacterial infection,[382] but usually it is associated with congenital heart disease, intravenous catheters, or intravenous drug abuse.[72,379] A bicuspid aortic valve is recognized as an important risk factor for the development of infective endocarditis, especially in elderly men.[345] The underlying heart diseases in 266 pediatric cases of infective endocarditis are listed in Table 26-1.[256]

*References 50, 344, 354, 361, 395, 396.

A cooperative study on the natural history of aortic stenosis, pulmonary stenosis, and ventricular septal defect reported data from a controlled pediatric population collected over a period of 4 to 15 years.[178] In patients not undergoing surgical correction, the risk of acquiring endocarditis by 30 years of age in those with ventricular septal defects was 9.7 percent versus 1.4 percent for aortic stenosis and 0.9 percent for pulmonic stenosis. Aortic valvotomy in children with aortic stenosis actually increases the relative risk, whereas successful repair of ventricular septal defect significantly decreases long-term susceptibility to infective endocarditis.[179] Similarly, endocarditis is an extremely rare occurrence after ligation of patent ductus arteriosus has been performed. At present, palliative systemic-to-pulmonary shunting is the surgical procedure most often complicated by infective endocarditis.[461] In a review of 115 patients with tetralogy of Fallot, Kaplan and colleagues[258] reported an 8 percent incidence of infective endocarditis after placement of a Pott shunt.

The increasing use of prosthetic valves and valved conduit repairs in children with complex heart disease may lead to a larger number of cases of infective endocarditis in the future.[257,265,296,529,535] Most medical centers report an incidence of prosthetic valve endocarditis of 2 to 4 percent after surgery,[61,181,456,498] with the aortic and mitral valves affected most frequently.[237,323]

Older studies arbitrarily divided prosthetic valve endocarditis into two categories—early and late—based on whether the infection occurred within 60 days of valve placement or later.[36] The rationale for categorizing by time was based on apparent differences in bacteriologic, pathogenetic, and prognostic associations. So-called early cases most often were caused by coagulase-negative staphylococci (CONS), gram-negative bacilli, and fungi, whereas oral and enterococcal streptococci, along with staphylococci, predominated in late cases.[262] These older reports suggested that early cases were acquired by contamination of an intraoperative valve or were secondary to postoperative extracardiac infections, whereas late cases were acquired by the same mechanisms as native-valve endocarditis. Nosocomial bacteremia that develops at any time after the patient has undergone valve placement is a significant risk factor for development of endocarditis.[141,335,548] Finally, the mortality rate was thought to be higher in early versus late infection.

However, more recent studies have blurred this arbitrary time distinction between early and late prosthetic valve endocarditis.[61,237] The risk probably is highest in the first 6 to 12 months and decreases to its lowest point beyond 1 year after valve replacement. CONS are the dominant organisms both before and after the 60th postoperative day.[61,261] Clinical and epidemiologic data also suggest that prosthetic valve infection caused by staphylococci within the first year after placement probably is acquired at the time of surgery.[36] Identified risk factors for the development of prosthetic valve endocarditis in adults include native valve endocarditis, black race, male sex, a mechanical (vs. biologic) prosthesis, and prolonged cardiopulmonary bypass time[237]; no comparable information is available for children.

Mitral valve endocarditis occurs frequently on an anatomically normal valve in patients with other predisposing factors.[154] An association between mitral valve prolapse and infective endocarditis has been recognized in adults and children. This heart lesion is detected with increasing frequency in adolescent girls and may be only one component of a developmental syndrome.[481] In adults, 40 to 50 percent of cases of infective endocarditis associated with isolated insufficient mitral valves occur in patients with mitral prolapse.[93] In some series of native valve endocarditis, mitral valve prolapse has been the most common underlying lesion.[345] The reported incidence of infective endocarditis in patients with mitral valve prolapse has varied markedly among studies, from low rates of 14 per 100,000 per year to 5 of 58 patients monitored prospectively for 9 to 22 years.[213] A retrospective epidemiologic analysis involving matched cases and controls yielded an odds ratio of 8.2, indicative of a substantially higher risk for development of endocarditis in patients with mitral valve prolapse than in normal controls.[90]

That the risk of developing infective endocarditis is not uniform for all patients with mitral valve prolapse has become apparent. The risk is increased in patients with a preexisting systolic murmur (but not for those with an isolated click and no murmur), echocardiographically demonstrated regurgitation, and valvular redundancy.[100,322,333] The signs and symptoms of endocarditis associated with mitral valve prolapse may be more subtle than those of other types of left-sided endocarditis.[154,393] However, significant complications are relatively common occurrences and sometimes require valve replacement during the acute illness or during convalescence.[20,505]

Fungal endocarditis is a rare disorder in children but should be suspected in certain clinical and epidemiologic settings. It is more likely to occur after cardiac surgery and rarely occurs on native heart valves. It occurs more commonly in neonates treated in intensive care settings than in older children.[98] Other predisposing factors include (1) the presence of an indwelling vascular catheter, (2) prolonged use of antibiotics, (3) intrinsic (immunodeficiency diseases, malignancy, malnutrition) or extrinsic (corticosteroids, cytotoxic drugs) immunosuppression, (4) bowel surgery resulting in transient fungemia, (5) intravenous drug abuse, and (6) preexisting or concomitant bacterial endocarditis.

Many conditions other than structural heart disease predispose children to the development of infective endocarditis. The most important is the presence of an indwelling central venous catheter, especially in patients who are seriously ill or immunocompromised.[172,180,306,542,572] The catheter acts as a foreign body and presumably causes microscopic damage by abrading endocardial and valve surfaces; such damage results in nonbacterial thrombotic vegetation.[27] Infection of intracardiac pacemaker wires also can lead to endocarditis.[14] Infection acquired during the placement procedure and infection of the pacemaker pouch are most common. Infective endocarditis, usually of the tricuspid valve, has developed in children with ventriculoatrial shunts placed for the treatment of hydrocephalus.[256] In patients with arteriovenous fistulas created for hemodialysis, bacterial vegetations may develop in the fistula and on heart valves.[298,439] Rarely, penetrating wounds or foreign bodies can initiate endocarditis.[218,332] Piercings of various body parts also have been associated with endocarditis.[2,432] One important group of patients with an increased risk for development of infective endocarditis is intravenous drug users.[340,575] In this group of patients, two thirds have no evidence of underlying heart disease. A predilection for involvement of the tricuspid valve, followed by the mitral and aortic valves, has been noted.[168] Radiographic evidence of septic pulmonary emboli and signs of tricuspid insufficiency dominate the clinical findings.[474] Within this group of patients, increased rates of infective endocarditis and mortality are associated with infection by human immunodeficiency virus (HIV), particularly as CD4 cell counts fall to less than 200/mm^3.[425]

Several recent studies have found an apparent shift in the epidemiology of pediatric infective endocarditis toward a higher proportion of children without preexisting heart disease, which accounted for 35 to 58 percent of all the infective endocarditis cases.[112,294,309] In these patients, *S. aureus* was the most common causative organism and delay in diagnosis was common.

Although the incidence of infective endocarditis in children may be rising, the prognosis has improved dramatically during the past several decades. Current mortality rates usually are close to 10 percent.[370,461,480] Most survivors remain hemodynamically stable at long-term follow-up.[157,480] However, patients who experience infective endocarditis appear to be at higher risk for developing recurrent endocarditis than are those with similar cardiac abnormalities who have not had previous endocarditis.[498] The patient's functional class before treatment appears to be most predictive of long-term functional status. In one study, 22 percent of children who survived infective endocarditis required surgery related to the infection, including vegetectomy, evacuation of a hematoma, atrioventricular valve replacement, and placement or replacement of a graft or intracardiac shunt.[461]

PATHOPHYSIOLOGY

Clinical observations, autopsy studies, and work with experimental animal models have demonstrated that the occurrence of several independent events is required for the development of subacute infectious endocarditis. The endocardial surface usually is disrupted by stress or injury commonly caused by the turbulence of blood. This surface damage results in the deposition of fibrin and platelets, which form nonbacterial thrombotic vegetations. If bacteria adhere to these deposits, infective endocarditis will result. The surface of the infected vegetation becomes protected by a cover of fibrin and platelets. A tremendous proliferation of organisms (as many as 10^9 colony-forming units per gram) may ensue.[127] The protective sheath isolates the organisms from the action of host neutrophils and antibiotics. The clinical manifestations and complications of infective endocarditis are related to both the hemodynamic changes caused by local infection and the occurrence of embolization and metastatic infection.

In experimental animals, the valvular surface must be damaged, usually by an intravenous catheter, to produce infective endocarditis.[21] The first step in the pathogenesis of subacute infective endocarditis in humans is the development of hemodynamic factors that favor endocardial damage. In an autopsy study of 1024 patients with infective endocarditis, Lepeschkin[299] showed that the location of the endocardial lesions correlated with the impact of pressure; this finding makes a strong argument for the role of mechanical stress as a critical factor in the evolution of the lesions. When associated with valvular insufficiency, infective endocarditis usually occurs on the atrial surface of the mitral valve and the ventricular surface of the aortic valve. Injection of a bacterial aerosol into the air stream passing through a Venturi tube demonstrates how high pressure drives an infected fluid into a low-pressure sink.[446] This process establishes maximal deposition of bacteria in the low-pressure sink immediately beyond the orifice. Mitral insufficiency creates a Venturi effect when blood is driven from the high-pressure left ventricle into a low-pressure atrium; maximal deposition occurs around the mitral annulus on the atrial side. Similarly, with aortic valve insufficiency, the high-pressure source is the aorta and the low-pressure sink is the left ventricle, which leads to deposition on the ventricular surface of the valve.

Lesions also are created more directly by a jet stream causing endocardial damage. For example, in a small, restrictive ventricular septal defect with a left-to-right shunt, a Venturi effect leads to the development of lesions on the right ventricular septal side of the defect, whereas secondary lesions created by the jet effect are located on the right ventricular wall opposite the defect.[567] Heart defects with a surface area sufficiently large to prevent a significant pressure gradient and those in which smaller volumes minimize the gradient do not create the jet and Venturi effects. This difference helps to explain the rarity of endocarditis in patients with atrial septal defects and the increased risk of infection complicating small, but not large, ventricular septal defects.

Once endocardial damage has occurred, collagen is exposed and platelet and fibrin deposition ensues in a manner analogous to formation of the primary plug of normal hemostasis after vascular injury.[246,568] The sterile platelet-fibrin thrombus that is formed subsequently is referred to as a nonbacterial thrombotic vegetation.[315,401] In experimental animals, many exogenous stresses, including exposure to cold, high altitude, high cardiac output states, hormonal manipulations, and passage of a sterile catheter across a heart valve, lead to formation of this lesion. Formation of the vegetation reflects two pathogenic mechanisms: hypercoagulability and endothelial damage.[474] To establish experimental infective endocarditis without initial formation of the vegetation is nearly impossible. Microscopic examination demonstrates that this lesion is the one to which microorganisms attach during the early stages of experimental endocarditis. Nonbacterial thrombotic vegetations have been found in both adults and children with malignancy, chronic wasting diseases, uremia, connective tissue diseases, and congenital heart disease and after the placement of intracardiac catheters,[341,439] and they have been associated with embolism and infarction in distant organs.[46]

Once a nonbacterial thrombotic vegetation has been established, transient bacteremia or fungemia may result in colonization of the lesion. Transient bacteremias are common occurrences, especially with traumatization of a mucosal surface. The incidence of bacteremia in adults and children after various procedures is listed in Table 26-2.[139,444] The bacteremia usually is of low grade and is proportional to the amount of trauma produced by the procedure and the number of organisms inhabiting the surface. In addition, "silent" bacteremia probably occurs frequently. Many persons have circulating antibodies to their own oral flora, as well as an increase in peripheral T cells sensitized to the flora of their dental plaque.[474]

TABLE 26-2 **Bacteremia After Various Procedures in Adults and Children**

Initiating Event	Percentage of Positive Blood Cultures (%)	Predominant Organisms
Dental extraction (children)	30-65	*Streptococcus*, diphtheroids
Chewing gum, candy, paraffin	0-51	*Streptococcus, Staphylococcus epidermidis*
Tooth brushing	0-26	*Streptococcus*
Tonsillectomy	28-38	*Streptococcus, Haemophilus*, diphtheroids
Bronchoscopy (rigid scope)	15	*Streptococcus, S. epidermidis*
Bronchoscopy (fiberoptic)	0	
Orotracheal intubation	0	
Nasotracheal intubation/suctioning	16	*Streptococcus*, aerobic gram-negative rods
Sigmoidoscopy/colonoscopy	0-9.5	*Enterococcus*, aerobic gram-negative rods
Upper gastrointestinal endoscopy	8-12	*Streptococcus, Neisseria, S. epidermidis,* diphtheroids, other
Percutaneous liver biopsy	3-14	Pneumococcus, aerobic gram-negative rods, *Staphylococcus aureus*, other
Urethral catheterization	8	Not stated

Some children with congenital heart disease may be at increased risk for having gingival colonization and subsequent development of bacteremia with organisms associated with infectious endocarditis, such as the HACEK *(Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae)* microbes.[501]

The ability of microorganisms to adhere to the platelet-fibrin thrombus is a critical factor in the development of infective endocarditis.[105,202,246] In a canine model, *S. aureus* and the viridans streptococci, which frequently cause infective endocarditis, adhere more readily to normal aortic leaflets than do organisms uncommon in endocarditis.[191] Within isolates of *S. aureus*, strains devoid of microencapsulation are less capable of inducing endocarditis in an experimental model than are encapsulated strains.[22] Specific products released by these organisms, including dextran, mannan, teichoic acid, and slime, may enhance their ability to colonize the vegetation.[246,274] The amount of dextran produced by various viridans streptococci in broth correlates with both their adherence and their ability to produce endocarditis in the rabbit model.[362,477] *Candida albicans* is readily adherent and produces infective endocarditis in rabbits more easily than does *C. krusei*, a nonadherent yeast rarely implicated in human infective endocarditis.[475] In addition, endocarditis-producing strains of streptococci and staphylococci are more potent stimulators of platelet aggregation than are other bacteria that do not produce infective endocarditis.[89,211,362] This action may accelerate the formation of an infected vegetation or may increase the removal of organisms from the circulation. The importance of adherence by organisms has been studied by preincubating organisms with many classes of antibiotics. After incubation at subinhibitory concentrations, adhesion of streptococcal species to fibrin-platelet matrices and damaged canine valves is decreased.[478] Antibiotics may prevent development of infective endocarditis by both bacterial killing and inhibition of adherence to the vegetation.[185]

Host tissue factors undoubtedly play an important role in adherence of bacteria to the developing thrombus. Activation of the coagulation system ensues once bacteria become adherent to a nonbacterial thrombus. Some organisms that produce endocarditis may be able to initiate procoagulant activity through microbial enzymes. Activation of the intrinsic coagulation pathway is triggered by exposed connective tissue components and platelet aggregation.[274] However, activation of the extrinsic coagulation pathway probably is the major stimulus for growth of vegetations. Elements of the extracellular matrix, including fibronectin, laminin, and collagen, have been shown to facilitate the adherence of bacteria on fibrin-platelet matrices.[516,541] Fibronectin may be the host receptor for organisms within the nonbacterial thrombotic vegetation.[285,317] Laminin-binding proteins have been found on the cell walls of organisms recovered from patients with endocarditis.[495]

The platelet-organism interaction is complex and not understood completely. *Streptococcus sanguinis* produces two cell surface antigens that promote platelet aggregation: a class I antigen promotes adhesion of *S. sanguinis* to platelets, whereas coexpression of a class II antigen promotes platelet adhesion or aggregation.[212] The induced platelet aggregation appears to be an important determinant of further development of vegetation and progression of disease in experimental endocarditis. In addition, production of streptococcal exopolysaccharide inversely correlates with platelet adhesion while inhibiting aggregation, thus indicating that surface molecules may enhance endocarditis at only certain pathogenic steps.[513] Platelets also may be involved in host defense within the vegetation. After exposure to thrombin, platelets may release microbicidal proteins with bactericidal activity against some gram-positive cocci; resistance to these proteins may be a virulence factor for *S. aureus* in the development of endocarditis.[389,585]

As bacterial colonization of a nonbacterial thrombotic vegetation progresses, it enlarges by further bacterial proliferation and platelet-fibrin deposition (Fig. 26-1).[365] Kissane[279] described three histologic zones: (1) necrotic endocardium; (2) a broad zone of bacterial colonies, pyknotic nuclear debris, and fibrin; and (3) a thin coating on the surface of fibrin and leukocytes. The location of bacterial colonies below the surface and the minimal infiltration by phagocytic cells create an environment of impaired host resistance that results in extreme bacterial proliferation. The structure of the vegetation diminishes the penetration of antibiotics into the bacterial layer. In addition, the metabolic activity of bacteria within this lesion is slowed, thus rendering antibiotics less effective. The formation of vegetations and erosion of heart valves may cause valvular incompetence and thereby may result in cardiac failure.

Immunopathologic factors may have important roles in both the development and sequelae of infective endocarditis.[37] The susceptibility of a gram-negative bacillus to complement-mediated bactericidal activity is critical to its potential to create endocarditis.[126] Gram-positive cocci are a more frequent cause of infective endocarditis than are gram-negative bacilli. Gram-positive organisms are resistant to this bactericidal activity; phagocytosis is required for killing.

The frequent presence of hypergammaglobulinemia, splenomegaly, and monocytes in the blood of patients with infective endocarditis indicates stimulation of the humoral and cellular immune systems. Macroglobulins, cryoglobulins, and agglutinating, opsonic, and complement-fixing antibodies have been associated with infective endocarditis.[221,293] Studies in animals preimmunized with heat-killed streptococci before aortic valve trauma and infection are induced suggest that circulating antibody has a protective role.[476,549] However, antibody to *S. aureus* or *Staphylococcus epidermidis* does not prevent the development of endocarditis in immunized animals, perhaps because this antibody does not enhance opsonophagocytosis.[474] The continuous antigenic challenge created by intravascular organisms leads to increased production of specific antibody (including opsonic, agglutinating, and complement-fixing antibodies), cryoglobulins, macroglobulins, and antibodies to bacterial heat shock protein,[428] as well as to the subsequent formation of circulating immune complexes. These complexes are found with increased frequency in patients with a long duration of illness, hypocomplementemia, extravalvular

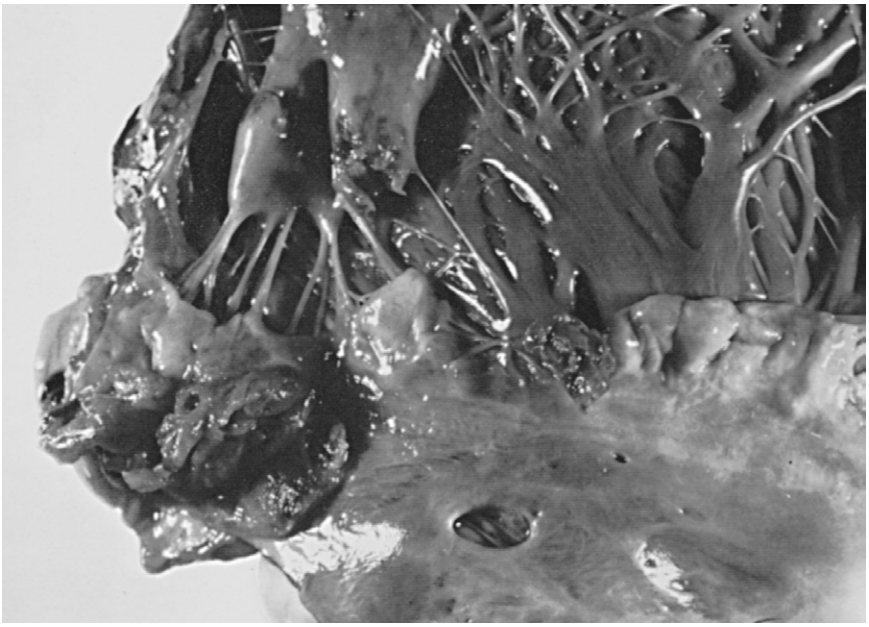

FIGURE 26-1 ■ Subacute endocarditis of the mitral valve with vegetation and rupture of the papillary muscle caused by *Staphylococcus aureus.* (Courtesy of Dr. Edith P. Hawkins, Texas Children's Hospital, Houston.)

manifestations, and right-sided disease.[39] Quantitative levels of circulating immune complexes may be helpful in distinguishing endocarditic from nonendocarditic sepsis and in monitoring anti-infective therapy. Effective treatment usually leads to a prompt decrease in these levels,[38] whereas relapses may be characterized by rising titers.[266] The diffuse glomerulonephritis occasionally noted with infective endocarditis is caused by subepithelial deposition of immune complexes and complement.[197] Immune complexes can be demonstrated in some diffuse purpuric lesions seen with endocarditis.[316] Bacterial antigens have been found within these complexes.[234]

Further evidence of stimulation of the immune system in infective endocarditis is the development of rheumatoid factor in approximately 50 percent of adults with disease lasting longer than 6 weeks.[574] Titers of rheumatoid factor correlate with hypergammaglobulinemia and, as with immune complex levels, decrease with therapy and increase during relapse. The role of rheumatoid factor in the disease process is unknown, but it may be involved by blocking immunoglobulin G opsonic activity, stimulating phagocytosis, or accelerating microvascular damage.[474] Antinuclear, antiendocardial, antisarcolemmal, and antimyolemmal antibodies also have been identified in patients with infective endocarditis; their role in pathogenesis is unclear.[325]

The pathologic changes that occur in the heart in association with infective endocarditis are secondary to local extension of the infection. The vegetations vary from a millimeter to several centimeters; frequently they are singular, but they may be multiple. Valvular stenosis may result from large lesions. Vegetations secondary to certain organisms, especially *Candida*, *Haemophilus*, and *S. aureus* in acute cases, often are large and friable, with a propensity for embolization.[586] Ulcerative lesions may occur and may lead to perforation of the valve and subsequent congestive heart failure. Other local complications include rupture of the chordae tendineae or papillary muscle (see Fig. 26-1), valve ring abscess with subsequent fistula formation and pericardial empyema,[51,67] aneurysms of the sinus of Valsalva or ventricle,[80,173,471] myocarditis, and myocardial infarction.[145] Persistent fever occurring during appropriate medical therapy for infective endocarditis may reflect a persistent vegetation, especially with right-sided disease, or extension of infection into a valve ring and adjacent structures.[120] In such cases, surgery frequently is required.

The pathologic changes in distant organs usually are secondary to embolization with subsequent infarction or metastatic infection. In many cases of infective endocarditis, the causative organism is of low pathogenicity; infections caused by septic emboli often are low-grade because of the reduced propensity of these organisms to invade tissue. However, the emboli in acute *S. aureus* endocarditis frequently cause severe metastatic infections and overwhelming sepsis. Emboli from right-sided heart lesions lodge in the lungs and cause pulmonary infarcts and abscesses, which usually are small and multiple. Left-sided lesions may embolize to any organ but most commonly affect the brain, kidney, spleen, and skin.[280,383] Cerebral emboli have been detected in 30 percent of cases in adults and children and have caused infarction, abscess, mycotic aneurysm, subarachnoid hemorrhage, meningitis, and acute hemiplegia of childhood.* Kidney abscess is a rare occurrence, but infarcts are noted in most patients at autopsy.[357] Amyloidosis involving primarily the kidneys is a rare complication of chronic infective endocarditis.[210] Splenic abscess also is a rare event but can be a fatal complication if undetected.[250] The most common manifestation of embolization to the skin is petechiae. Janeway lesions are septic emboli consisting of bacteria, neutrophils, necrosis, and subcutaneous hemorrhage. Osler nodes are areas of thrombosis and necrosis. They may be related to both immune complex deposition and septic emboli.[5]

CLINICAL MANIFESTATIONS

The signs and symptoms of infective endocarditis are determined by the extent of local cardiac disease, the continuous bacteremia, and the degree of involvement of distant organs as a result of embolization, metastatic infection, and circulating immune complexes.[25] Consequently, the clinical findings are highly variable and mimic those of many other diseases.[78,459] Unexplained embolic phenomena in any organ should suggest the diagnosis of endocarditis, especially in children with known heart disease. Patients with acute bacterial endocarditis initially may be seen with florid sepsis; the endocarditis is diagnosed at autopsy. The indolent manifestations of subacute endocarditis may evolve for weeks or months before medical care is sought. Endocarditis frequently occurs in children with preexisting heart disease, so subtle changes in cardiac function may be difficult to detect early in the course. The frequency of the major clinical manifestations of bacterial endocarditis in infants and children is listed in Table 26-3.

Fever is the most common symptom of infective endocarditis, but it is absent in 10 percent of cases. It usually is of low grade and has no specific pattern. Chills may accompany the fever, but they rarely are seen in children. Persistent fever during antimicrobial therapy is an uncommon occurrence. Prolonged (≥2 weeks) fever is associated with certain etiologic agents (*S. aureus*, gram-negative bacilli, fungi), with culture-negative endocarditis, and with complications such as embolization of major vessels, intracardiac or peripheral abscess, tissue infarction, a need for cardiac surgery, and a higher mortality rate.[52,295] Nonspecific symptoms such as malaise, anorexia, weight loss, and fatigue are common findings. Arthralgia occurs in 24 percent of patients. The arthralgia frequently is multiple and most commonly affects the large joints. Although adults initially may have synovitis,[87] this finding is rare in children. Osteoarticular infection in association with infective endocarditis in adults occurs almost exclusively in intravenous drug users.[470] It is seen very rarely in children except those with disseminated *S. aureus* infection. Gastrointestinal complaints are noted in 16 percent of cases and include nausea, vomiting, and abdominal pain. Chest pain occurs in approximately 10 percent of older children and generally is mild and nonspecific. Although chest pain usually is related to diffuse myalgias, it may be secondary to pulmonary complications or cardiac lesions, especially if the tricuspid valve is involved.

Heart murmurs occur in more than 90 percent of children with infective endocarditis, but most patients have underlying heart disease with existing murmurs. The appearance of a new murmur or appreciation of a significant change in a previous one occurs in only 25 percent of cases. Significant blood flow turbulence caused by compromised valvular function must have occurred for a murmur to be detected or to change. The frequent absence of changes in the cardiac examination early in the disease contributes to the long average delay in establishing the diagnosis, especially in children with preexisting heart disease. Congestive heart failure occurs in 30 percent of children with infective endocarditis and is especially common in those in whom a new murmur of valvular insufficiency develops. Endocarditis should be suspected in any child who has rheumatic or congenital heart disease and unexplained deterioration in cardiac function. Although valvular regurgitation is the most common hemodynamic complication of endocarditis, significant obstruction of a valve or shunt requiring rapid surgery rarely occurs.[79]

Neurologic signs and symptoms are reported in approximately 20 percent of children with endocarditis. These signs and symptoms may dominate the clinical findings, especially in patients with endocarditis caused by *S. aureus*.[205,463] The sudden development of cerebral lesions in an infant or child should suggest this diagnosis. The manifestations are those that commonly accompany a cerebral infarct or abscess, namely, acute hemiplegia of childhood, seizures, ataxia, aphasia, sensory loss, focal neurologic deficits, and alterations in mental status.[64] They may be the initial features of endocarditis or may occur years after the infection has been eradicated.[590] Mycotic aneurysms of the cerebral vessels occur rarely in cases of pediatric endocarditis.[68] They usually are single, small, and peripheral but may lead to subarachnoid hemorrhage. Whereas computed tomographic scanning of the brain is useful for delineating central nervous system involvement in patients with infective endocarditis, magnetic resonance imaging may be more sensitive for detecting small infarctions and changes secondary to cerebral edema.[44] Other neurologic manifestations associated with endocarditis include cranial nerve palsies,

TABLE 26-3 **Clinical Manifestations of Bacterial Endocarditis in Children**

Symptom	Average (%)	Range (%)	Physical Finding	Average (%)	Range (%)
Fever	90	56-100	Splenomegaly	55	36-67

Data from references 53, 94, 96, 169, 248, 284, 337, 391, 459, 490, 497, 521, 530, and 553.

neuropathy, visual changes, choreoathetosis, seizures, and toxic encephalopathy.

Splenomegaly, a common manifestation of endocarditis in children, occurs in 55 percent of cases. It is found frequently in patients with long-standing disease and other evidence of immune system activation. The spleen generally is nontender and may be associated with mild hepatomegaly. Splenic infarction and abscess are rare events but should be suspected in patients with left upper quadrant abdominal pain that radiates to the left shoulder, a pleural friction rub, or left pleural effusion.

Skin manifestations occur less commonly in children than in adults.[316] Clubbing is found in 10 to 20 percent of children with endocarditis but frequently is related to underlying heart disease. Petechiae are noted in approximately one third of patients, especially those with long-standing disease. These lesions are found most commonly on the extremities, oral mucosa, and conjunctivae. Splinter hemorrhages are linear red or brown streaks seen in the nail beds. They are present in only 5 percent of children with endocarditis and are associated with other conditions.[276] Three other types of lesions are more specific for infective endocarditis but occur in only 5 to 7 percent of patients: Osler nodes, which are small (2 to 10 mm), painful nodular lesions found in the pads of the fingers or toes[5]; Janeway lesions, which usually are painless hemorrhagic macular plaques that frequently occur on the palms and soles[143]; and Roth spots, which are small, pale retinal lesions associated with areas of hemorrhage located near the optic disk.

Other than fever and, perhaps, splenomegaly, no single sign or symptom occurs in more than 50 percent of children with endocarditis. That no classic clinical manifestation exists for this disease is obvious because the chance that even three or more signs will be present is extremely low. The appearance of any one of these clinical features in a child with predisposing heart disease should raise suspicion of infective endocarditis and should lead to an appropriate diagnostic evaluation.[80]

The clinical findings of infective endocarditis in infants and neonates are less specific than are those in older children. The onset more often is acute and related to overwhelming infection.[249,348] In the preantibiotic era, these children often had other foci of infection, such as osteomyelitis, meningitis, and pneumonia, that dominated the clinical picture. The widespread use of antibiotics since 1941 has caused a decrease in the number of cases of infective endocarditis secondary to other suppurative infections.[348] Although early studies concluded that congenital heart disease was not an important predisposing factor to endocarditis in infants, more recent reports suggest that it is. At present, infants with heart defects undergo corrective and palliative surgery at a younger age than in the past. Infants in whom postoperative endocarditis does develop probably will have clinical findings more similar to those in older children.

Infective endocarditis is an uncommon occurrence in neonates and frequently is associated with indwelling vascular catheters.[172,334] It may affect the tricuspid valve and have a fairly "silent" clinical manifestation. Persistent bacteremia or fungemia should lead to a search for a cardiac focus of infection. Deterioration in pulmonary function, coagulopathies, thrombocytopenia, and low-grade murmurs often develop in neonates. Skin abscesses and hepatomegaly also are common findings. The prognosis of infective endocarditis associated with neonatal intensive care usually is favorable, perhaps because the diagnosis often is established relatively early and antibiotics are given rapidly.

Reported series of infective endocarditis in children with prosthetic valves are scarce. In early stages of disease, fever may be the only finding because the other signs of endocarditis are masked by the medical and surgical complications occurring in the immediate postoperative period. Late infections generally produce clinical findings similar to those in native valve endocarditis. Clinical evidence of systemic embolization occurs in as many as 40 percent of patients.[82] Neurologic complications carry a particularly poor prognosis for survival.[272] A new or changing murmur often indicates valvular insufficiency caused by a paravalvular leak. Florid cardiac failure is the major manifestation if local infection or an abscess creates valve instability and acute, severe regurgitation.

The signs and symptoms of infective endocarditis in intravenous drug users may be similar, but these patients have several more distinctive features of their illness. Two thirds of these patients have no predisposing heart disease. The valve most commonly affected is the tricuspid, which leads to a predominance of pulmonary signs and symptoms resulting from pleural effusion, pulmonary infarction, and lung abscesses. Signs of tricuspid insufficiency (gallop rhythm, pulsatile liver, regurgitant murmur) are found in one third of cases.[474] Many patients have extracardiac sites of infection that are helpful in establishing the diagnosis.[528]

LABORATORY FINDINGS

The most important diagnostic procedure is the blood culture. Because many bacteria that usually are not pathogenic cause infective endocarditis, scrupulous aseptic technique must be used to distinguish causative agents from contaminants.[404] The yield of organisms is not increased by obtaining blood from arterial puncture or cardiac catheterization.[40] The bacteremia usually is of low grade and continuous. The first two cultures yield the organism 90 percent of the time; in two thirds of cases, all blood cultures are positive.[571] Therefore, isolated positive cultures generally are not significant. Previous outpatient antibiotic therapy may change the yield significantly.[270] In one study, culture positivity in cases of proven endocarditis was 64 percent in patients who received antibiotics before blood was drawn for culture versus 100 percent in patients without exposure to antibiotics.[405]

When *Candida* endocarditis is suspected, several additional points should be considered. Isolation of *Candida* spp. may require incubation for 1 week or longer. All blood cultures from a patient with *Candida* endocarditis may not be positive, in contrast to the usual situation with bacterial endocarditis; several positive cultures may be interspersed among negative cultures. In patients with fungal endocarditis, *Candida* is isolated commonly from

other infected sites, such as urine, sputum, synovial fluid, cerebrospinal fluid, lymph nodes, and bone marrow.[465]

Three to five samples of blood for culture should be obtained from different sites within the first 24 hours in children with suspected endocarditis. Although difficult to obtain in smaller children, 3 to 5 mL of blood per culture is desirable for optimal yield. The samples should be injected into thioglycolate and trypticase soy (or brain-heart infusion) broth and held for at least 3 weeks to detect slow-growing organisms. If gram-positive cocci grow in the broth but fail to grow on subculture, nutritionally variant streptococci should be suspected and subculture should be performed on media with either L-cysteine or pyridoxal phosphate.[65,503]

Negative blood cultures are noted in 10 to 15 percent of patients with clinically diagnosed endocarditis.[544] However, when patients have not received antibiotic therapy previously and blood for culture is obtained properly, these cases account for less than 5 percent of the total. Potential reasons for negative cultures include the following: (1) right-sided endocarditis; (2) previous administration of antibiotics; (3) fungal (especially *Aspergillus*) endocarditis; (4) endocarditis caused by *Bartonella* spp., rickettsiae, chlamydiae, or viruses; (5) mural endocarditis; (6) slow growth of organisms (*Candida*, *Haemophilus*, *Brucella*, nutritionally variant streptococci); (7) anaerobic infection; and (8) nonbacterial thrombotic endocarditis or an incorrect diagnosis.[200,204,414,544] In some instances, intraleukocytic organisms may be seen in layered peripheral blood, even when cultures are negative.[422] If surgical resection of vegetations or valve replacement is performed, a cause may be demonstrated by appropriate histologic examination and stains for bacteria and fungi.[365] Organisms also may be isolated from extracardiac sites (bone marrow, urine).

Many nonspecific laboratory findings are abnormal in patients with infective endocarditis (Table 26-4). The total white blood cell count rarely is helpful, but peripheral eosinophilia may be seen with Loeffler endocarditis.[220] The erythrocyte sedimentation rate is elevated in 80 to 90 percent of cases. However, frequently it is normal or low when congestive heart failure or renal failure is present. Serum C-reactive protein levels usually are elevated initially and return to normal during the course of successful therapy.[342] An increase during therapy may result from treatment failure, but it can also be caused by drug allergy or intercurrent infection. Rheumatoid factor rarely has been measured in a series of pediatric patients, but when measurements have been made, they have been positive in 25 to 50 percent of children with endocarditis. A positive test may be a diagnostic aid in cases of culture-negative endocarditis when other causes are excluded. Serial measurements may provide evidence of efficacy of therapy, although a fall in the titer of rheumatoid factor may lag behind the clinical and bacteriologic response.[561] Hypocomplementemia is seen in association with glomerulonephritis. Anemia is present in approximately 40 percent of patients, especially those with long-standing disease. Although hemolysis may occur in the areas of turbulence in the heart, more often it is anemia of chronic disease. Because many patients with cyanotic heart disease normally have a compensatory polycythemia, a serial drop in hematocrit is of more significance than is a single measurement. Leukocytosis occurs in a few patients, but leukopenia is a rare finding in the absence of acute endocarditis with overwhelming sepsis. Hematuria and proteinuria, present in 25 to 50 percent of cases, usually are secondary to microemboli in the kidneys and may be accompanied by "pyuria," casts, and bacteriuria.

Circulating immune complexes are present in most adults with subacute endocarditis, as measured by Raji cell radioimmunoassay[531] or the ^{125}I-Clq binding assay.[591] These immune complexes frequently are absent in acute endocarditis. Low levels of immune complexes have been found in 32 percent of adults with septicemia but not endocarditis, in 10 percent of normal controls, and in 40 percent of noninfected intravenous drug users.[39] However, levels higher than 100 μg/mL are correlated highly with the presence of endocarditis. Serial measurement of immune complex levels may aid in monitoring therapeutic efficacy.[38] Systematic investigation of immune complexes has been reported infrequently in children with endocarditis. When immune complexes have been sought, most patients, including two of three children with culture-negative endocarditis, have had significant levels.

When infective endocarditis is suspected but blood cultures remain negative, serologic testing for specific organisms may prove helpful. Several techniques measure antibody to teichoic acids, which are major components of the cell wall of *S. aureus*. These antibodies are present in more than 85 percent of adults with staphylococcal endocarditis, but the false-positive rate is as high as 10 percent.[380] False-negative results correlate with a short (<2 weeks) duration of illness. Specific information about the accuracy of this test in children is lacking, and the tests are not readily available. Serologic testing is available or under investigation for many other organisms that cause infective endocarditis, including *Bartonella*, *Brucella*, *Candida*, *Aspergillus*, *Histoplasma*, *Cryptococcus*, *Chlamydia*, and *Coxiella*.[160,162,253,277] In general, the usefulness of these tests in children with endocarditis is unproven. Some patients with nonspirochetal bacterial endocarditis who reside in locales endemic for Lyme disease have significantly elevated levels of antibodies reactive to *Borrelia burgdorferi*.[255] Diagnostic confusion may occur because the signs and symptoms of infective endocarditis and Lyme disease can be quite similar. Other techniques, such as broad-range polymerase chain reaction, have

TABLE 26-4 **Selected Laboratory Findings of Bacterial Endocarditis in Children**

Laboratory Finding	Average (%)	Range (%)
Positive blood culture	87	68-98
Elevated erythrocyte sedimentation rate	80	71-96
Low hemoglobin (anemia)	44	19-79
Positive rheumatoid factor	38	25-55
Hematuria	35	28-47

Data from references 52, 94, 169, 248, 284, 337, 490, 497, 530, and 553.

been used to identify *Bartonella* and other causative agents of endocarditis.[55,160,559]

Radiographic techniques have not been a great aid in establishing the diagnosis of infective endocarditis. The findings on plain chest radiographs are nonspecific, but evidence of complications, such as septic pulmonary emboli or congestive heart failure, may be helpful. Computed tomography may help in establishing the diagnosis of an infected shunt.[545] Immunoscintigraphy using technetium-labeled antigranulocyte antibodies may yield useful information when the echocardiographic findings are equivocal.[363] Cineangiography is the definitive method to determine the anatomic alterations in the heart resulting from infective endocarditis, but it rarely needs to be performed in children.

The electrocardiogram also is useful in the evaluation of patients with endocarditis because it detects arrhythmias and conduction disturbances that complicate the disease. Ventricular ectopy may be related to myocardial ischemia, myocarditis, or myocardial abscess. New conduction defects imply extension of infection beyond the valve ring into the myocardium. Any degree of atrioventricular block, a new left bundle branch block, or a new right bundle branch block with a left anterior hemiblock may represent extension of infection from the aortic valve into the ventricular septum. Junctional tachycardia, Wenckebach atrioventricular block, or complete heart block may be produced by extension of the infection from the mitral valve anulus into the atrioventricular node or proximal His bundle. In general, an unstable conduction block is more likely to develop in patients with aortic valve endocarditis than in those with mitral infection.[118]

Echocardiography has become a valuable adjunct to the diagnosis and treatment of endocarditis in children.* Color Doppler imaging is a sensitive modality for detection of valvular insufficiency, and the results may influence surgical and medical treatment decisions.[155] Echocardiography can be performed by the traditional transthoracic approach or the transesophageal approach.[419] The sensitivity and specificity of transthoracic echocardiography continue to be defined, with positive results obtained in 36 to 100 percent of children in various series of pediatric patients.†

In general, two-dimensional echocardiography is more sensitive than is the M-mode technique, especially in cases of right-sided endocarditis,[399] and it is superior in diagnosing complications of the destructive process.[25,355] The smallest vegetation detectable is approximately 2 mm, but the acoustic impedance of the mass relative to the surrounding structures is a more important factor than is size in identifying the vegetation. Echocardiography has identified vegetations in culture-negative cases.[267] Its accuracy in prosthetic-valve endocarditis is diminished by the difficulty in resolution around the prosthetic device.[374,507] Serial evaluation of valvular vegetations generally does not assist in assessing the efficacy of antibiotic therapy because diminution or disappearance of vegetations may take place long after successful medical treatment has been completed.[278,449,558]

The use of transthoracic echocardiography to predict the clinical course and need for operative intervention in patients with endocarditis is controversial.[8,190]A synopsis of many reports that have assessed the role of transthoracic echocardiography in the diagnosis and management of infective endocarditis suggests the following: (1) because of variable sensitivity among studies for detection of vegetations, a negative study does not rule out endocarditis, especially when foreign material is present within the heart; (2) false-positive studies are quite rare (the specificity is high); (3) the reliability of transthoracic echocardiography depends on the experience of the examiner and the technical adequacy of the study; (4) transthoracic echocardiography is valuable in assessing local complications of endocarditis on native valves; and (5) in most but not all studies, patients with a vegetation identified by transthoracic echocardiography have an increased risk for the development of systemic emboli and congestive heart failure.*

Although some investigators contend that the presence of a vegetation should hasten early surgery, most suggest that a positive echocardiogram is adjunctive evidence that should be considered along with other clinical parameters when considering surgical intervention. One study suggested that the relative risk for having embolic events associated with echocardiographically visualized lesions is microorganism dependent, with a significant attributable risk seen, for instance, in patients with viridans streptococcal infection.[499] The absence of a vegetation on transthoracic echocardiography may define a subset of patients at low risk for the development of embolic complications.

Transesophageal echocardiography has been studied extensively in adults with infective endocarditis.[104] It uses a 5-MHz phased-array transducer with Doppler and color flow encoding capabilities mounted on the tip of a flexible endoscope.[474] Biplane transesophageal echocardiography is considered the standard technique and is superior to transthoracic echocardiography because of improved spatial resolution, lack of acoustic interference from the lungs and chest wall, and closer proximity to posterior structures, such as the mitral valve and left atrium.[103] Multiplane transesophageal echocardiography facilitates and abbreviates the examination procedure and may be more accurate in providing the dimensions of a vegetation associated with infective endocarditis.[103,244]

Transesophageal echocardiography generally is well tolerated by children, even with the use of an adult probe (when the child's weight is more than 7 kg),[482] and rarely is associated with bacteremia.[102,289,418] Transesophageal echocardiography usually is more sensitive than is transthoracic echocardiography in the detection of intracardiac vegetations and is positive in 70 to 95 percent of adults with strongly suspected endocarditis.[371,489] One recent study showed that transesophageal echocardiography significantly increased the detection of vegetations in bigger (>60 kg) children but did not improve on the results of transthoracic echocardiography in smaller

*References 190, 241, 319, 346, 443, 468, 506.

children.[411] It is significantly more sensitive in the detection of vegetations and complications in infected prosthetic valves.[273,406,448,507,520] Transesophageal echocardiography is particularly useful for detecting an aortic root abscess or involvement of the sinus of Valsalva in adults, and it should be considered in children with aortic valve endocarditis and changing aortic root dimensions on a standard transthoracic echocardiogram.[155,346] It appears to be less helpful for detection of vegetations in right-sided endocarditis.[469] Although a negative transesophageal echocardiographic study does not exclude endocarditis,[494] the procedure should be considered for patients with suspected endocarditis and a negative transthoracic echocardiogram, when the transthoracic echocardiographic windows are suboptimal, and when perivalvular extension of infection is suspected.[15,230]

To aid in establishing the diagnosis of infective endocarditis, various sets of clinical criteria have been suggested. The von Reyn criteria were described in 1982, but echocardiographic findings were not included in the case definitions.[557] In addition, isolation of a typical infective endocarditis pathogen from blood cultures was not considered. New case definitions and diagnostic criteria were proposed by investigators from Duke,[129] and they have been modified subsequently (Tables 26-5 and 26-6).[288,305] The inclusion of echocardiographic and blood culture findings in these new criteria has resulted in more flexibility, a higher proportion of "definite" cases, and a more accurate reflection of current clinical practice.[351] These criteria have been validated in large series of infective endocarditis in adults and children.[114,129,215,442,467] In two pediatric series of clinically defined endocarditis, no cases were rejected by the Duke criteria, whereas 25 and 19 percent were rejected by the von Reyn criteria.[114,508] In one study, three of six pathologically confirmed cases were rated as only probable or rejected by the von Reyn criteria whereas all were definite by the Duke criteria.[114] However, a more recent study found that 12 percent of pediatric endocarditis cases were not classified as "definite" by the modified Duke criteria.[533] In addition, the presence of an indwelling venous catheter causing prolonged bacteremia may cause an overestimation of the rate of infective endocarditis using the Duke criteria.[42]

TABLE 26-5 **Definition of Terms Used in the Modified Duke Criteria for Infective Endocarditis**

Major Criteria

1. Positive blood culture
   a. Typical microorganisms for IE from ≥2 blood cultures
      (1) Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus or*
      (2) Enterococci, in the absence of another primary focus, *or*
   b. Persistently positive blood cultures, with recovery of a microorganism consistent with IE from
      (1) Blood cultures drawn ≥12 hours apart *or*
      (2) All of three or a majority of four or more separate blood cultures, with first and last drawn ≥1 hour apart
2. Evidence of endocardial involvement
   a. Positive echocardiogram for IE
      (1) Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation, *or*
      (2) Abscess *or*
      (3) New partial dehiscence of a prosthetic valve *or*
      (4) New valvular regurgitation (increase or change in preexisting murmur is not sufficient)

Minor Criteria

1. Predisposing heart condition or intravenous drug use
2. Fever ≥38°C (100.4°F)
3. Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
4. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
5. Microbiologic evidence: positive blood culture but not meeting major criteria as noted previously* or serologic evidence of active infection with organism consistent with IE

*Excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause IE.
HACEK, Haemophilus species, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, Kingella kingae; IE,* infective endocarditis.
From Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 2000;**30**:633–8.

MICROBIOLOGY

Many different microorganisms are capable of causing infective endocarditis in humans.[235] A list of the organisms isolated from patients in major pediatric series is presented in Table 26-7. Gram-positive cocci are the etiologic agents in 90 percent of cases in which an organism is isolated. Streptococci remain the bacteria isolated most frequently, although the percentage of cases caused by staphylococci and fungi has been increasing during the past 2 decades.[164,461,553,586] Polymicrobial infective endocarditis, especially in nosocomial settings, also appears to be increasing in incidence.[23] The characteristics of selected organisms and the type of disease that they produce are considered next.

Streptococci

Several terminologies have been used to classify streptococci. The Lancefield system defines groups (A, B, C, D, E, F, G, H) by serologic reactions. The viridans streptococci are α-hemolytic or nonhemolytic, may be Lancefield nontypeable (*Streptococcus anginosus* [formerly *S. milleri*], *S. mitior*, *S. salivarius*, most *S. mutans*, and *S. sanguinis*) or typeable (*S. bovis* group D, some *S. sanguinis* group H, some *S. anginosus* group F), and display similar characteristics in vivo. They are the most frequent etiologic agents in subacute infective endocarditis and cause 40 percent of cases in children. They may cause rapidly progressive invasive disease.[222,515]

Viridans streptococci are common pathogens in patients with underlying heart disease but are less common in postoperative patients. They are part of the

TABLE 26-6 Modified Duke Criteria for the Diagnosis of Infective Endocarditis

Definite

1. Pathologic criteria
   a. Microorganisms: demonstrated by culture or histology in a vegetation, in a vegetation that has embolized, or in an intracardiac abscess *or*
   b. Pathologic lesions: vegetation or intracardiac abscess present and confirmed by histology showing endocarditis
2. Clinical criteria (see Table 26-5)
   a. Two major criteria *or*
   b. One major and three minor criteria *or*
   c. Five minor criteria

Possible

1. One major criteria and one minor criterion, or
2. Three minor criteria

Rejected

1. Firm alternative diagnosis explaining evidence of IE *or*
2. Resolution of IE syndrome with antimicrobial therapy for ≤4 days *or*
3. No pathologic evidence of IE at surgery or autopsy with antibiotic therapy for ≤4 days

IE, infective endocarditis.

From Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 2000;**30**:633–8.

TABLE 26-7 Etiologic Agents of Bacterial Endocarditis in Children

Organism	Average (%)	Range (%)
Streptococci		
Viridans	40.3	17-72
Enterococci	4.0	0-12
Pneumococci	3.3	0-21
β-Hemolytic	2.7	0-8
Other	1.1	0-16
Staphylococci		
Staphylococcus aureus	23.8	5-40
Coagulase-negative	4.7	0-15
Gram-negative aerobic bacilli	4.0	0-15
Fungi	1.1	0-12
Miscellaneous bacteria	2.4	0-10
Culture-negative	12.6	2-32

indigenous flora of the human mouth and gastrointestinal tract, and procedures that disrupt mucosal integrity in these areas predispose patients to development of viridans streptococcal bacteremia. In the pediatric population, most blood and cerebrospinal fluid isolates of viridans and nonhemolytic streptococci are not from patients with infective endocarditis.[203] Most strains are exquisitely susceptible to penicillin, although resistance has been increasing related to previous administration of antibiotics.[282,301] Nutritionally variant viridans streptococci, reclassified as *Abiotrophia defectiva* or *Granulicatella* spp., are recognized as one cause of culture-negative endocarditis in children.* These organisms grow in broth but will not grow on subculture agar-based plates. Bacteriologic failure has occurred in 40 percent of reported cases of endocarditis caused by these organisms despite susceptibility to the antibiotics used.[25,503] Most viridans streptococci have low pathogenicity; however, the *S. anginosus* group has a predilection for suppurative complications.[376] The prognosis of endocarditis caused by nonenterococcal streptococci is excellent with good medical and surgical management; the cure rate is more than 90 percent, although complications (emboli, congestive heart failure) occur in as many as 30 percent of cases.

Enterococcal endocarditis occurs much less frequently in children than in adults[349,527,529] and accounts for only 4 percent of pediatric cases. The organism normally inhabits the gastrointestinal and genitourinary tracts; instrumentation of these areas may cause enterococcal bacteremia. More than 40 percent of adult patients have no underlying heart disease.[440] Endocarditis should be considered in all infants and children with unexplained enterococcal bacteremia. Although the incidence of enterococcal bacteremia appears to be increasing in some neonatal intensive care units, the incidence of associated endocarditis seems to be very low. Factors that may suggest endocarditis in patients with enterococcal bacteremia include (1) preexisting heart disease, (2) community acquisition, (3) a cryptogenic source, and (4) the absence of polymicrobial bacteremia.[326] Differentiation of enterococci from other group D streptococci *(S. bovis)* is important because their respective therapeutic approaches are different.

Endocarditis caused by β-hemolytic streptococci occurred more commonly in the preantibiotic era than today. Most cases are caused by Lancefield group B or G organisms,[1,17,63,171,566] whereas group C and A streptococci rarely cause endocarditis.[49,121,187,314,433] Group A, B, or C streptococcal infection may lead to large, bulky vegetations, easily seen by echocardiography, and to embolic complications.[18,360,464] Although group B streptococcal bacteremia is a common finding in neonates, endocarditis caused by this organism occurs rarely in this age group. Similarly, *S. pneumoniae* accounted for 10 to 15 percent of endocarditis cases in the preantibiotic era but currently causes less than 1 percent.[175,240,397] Pneumococcal endocarditis may involve either the aortic or the mitral valve.[135,184,537] In older studies, fewer than 50 percent of affected children had underlying heart disease, but in more recent series, most children have had existing heart disease.[236] The clinical course often is fulminant.[132,297,420] Concurrent meningitis or pneumonia (or both) occurs frequently. Valvular dysfunction and cardiac decompensation are common findings.[52,60,83] Early surgical intervention may be required because the mortality rate is 75 percent when medical management alone is used.[240]

Staphylococci

Staphylococci cause 20 to 30 percent of cases of infective endocarditis in children, but the relative incidence

*References 77, 146, 308, 384, 430, 445.

appears to be increasing, and in some series this organism has been more common than streptococci.[6,164] *S. aureus* is the etiologic agent in most cases of acute endocarditis and frequently infects normal heart valves.[165,369] The course often is fulminant when the mitral or aortic valve is involved, with frequent suppurative complications occurring both in the heart (myocardial abscess, pericarditis, valve ring abscess) and in other organs.[138,254,356] *S. aureus* is responsible for more than 50 percent of cases of endocarditis in intravenous drug users, but the disease tends to be less severe in these patients.[75,76] The origin of the infecting organism is the addict's own nose or skin, not the injection paraphernalia.[543] Endocarditis associated with indwelling vascular catheters or prosthetic valves frequently is caused by *S. aureus.*[245] Endocarditis must be suspected in any patient with *S. aureus* bacteremia, even when a peripheral focus of infection is present.[452] However, most patients with *S. aureus* bacteremia do not have endocarditis. The rise of methicillin-resistant *S. aureus* (MRSA) has rendered treatment more difficult but has had little impact on the rate of local complications.[228]

The incidence of endocarditis resulting from CONS is rising rapidly.[13] CONS is a common etiologic agent of endocarditis occurring after cardiac surgery,[271,310] and it is occurring more frequently on native valves.[84,85] This organism is the leading agent in prosthetic valve endocarditis, for which it causes 25 to 67 percent of early cases and 25 to 33 percent of late cases.[181,237,261] CONS endocarditis also has been associated with mitral valve prolapse and the use of intravascular catheters in premature neonates.[24,392] Although metastatic infection rarely occurs, CONS can be locally invasive; the mortality rate of prosthetic valve endocarditis caused by CONS approaches 75 percent when valve replacement is not performed.

Gram-Negative Organisms

Although gram-negative bacteria cause 4 to 5 percent of cases of infective endocarditis in children, the percentage of children with gram-negative enteric bacteremia in whom endocarditis develops is extremely low. Endocarditis should be suspected in patients with gram-negative infection when bacteremia persists despite administration of usually appropriate antibiotic therapy.[70] Burn patients,[232] immunosuppressed hosts, narcotic addicts, and patients with implanted endovascular devices[364] are at an increased risk for development of gram-negative endocarditis. However, in the early postoperative period after cardiac surgery, sustained gram-negative bacillary bacteremia commonly is caused by other foci of infection and does not imply the presence of endocarditis. Many species of gram-negative enteric organisms have caused infective endocarditis in children, but no clear pattern has emerged. Among the gram-negative organisms more commonly reported are *Brucella*, *Escherichia coli*, *Serratia*, *Klebsiella-Enterobacter*, *Salmonella*, and *Pseudomonas.** Endocarditis caused by *Salmonella* has been reported in patients with HIV infection.[152] It most often affects previously abnormal heart valves. Endocarditis is a rare complication of tularemia.[523] Cure of left-sided endocarditis caused by the Enterobacteriaceae seldom is achieved with medical therapy alone.[474] Most information about gram-negative enteric endocarditis is limited to case reports and general medicine reviews; discussion of individual organisms is beyond the scope of this review.

Other gram-negative organisms associated with infective endocarditis are the so-called HACEK coccobacilli.[108,147,229] These organisms caused 57 percent of cases of gram-negative endocarditis seen at the Mayo Clinic in Rochester, Minnesota, from 1958 to 1979.[177] Endocarditis caused by *Haemophilus influenzae* has been reported in only several children.[101,330] Cases caused by *H. parainfluenzae* and *H. aphrophilus* occur slightly more commonly.* They generally are seen in the setting of preexisting valvular disease and run a subacute course. However, central nervous system complications and emboli to major peripheral arteries are frequent occurrences.[86] Infective endocarditis caused by other organisms of the HACEK group is an extremely rare event in children.† Infection caused by *K. kingae* is being recognized more frequently due to recognition and enhanced culture techniques.[123,124,219] All the bacteria in this group are fastidious, may require 2 to 3 weeks for primary isolation, and need subculturing onto chocolate agar in an atmosphere of 5 to 10 percent carbon dioxide for optimal growth. These procedures should be performed in all cases of culture-negative endocarditis.

Neisseria gonorrhoeae was responsible for 10 percent of cases in the preantibiotic era, but fewer episodes have been reported since 1942.[151,238] This pathogen frequently attacks previously normal heart valves and is manifested as an acute illness.[524] Valvular destruction with a need for valve replacement occurs commonly. At present, nonpathogenic *Neisseria* spp. are isolated more frequently in endocarditis than are gonococci, but they usually attack abnormal or prosthetic valves.‡ Although 1 percent of cases of infective endocarditis in adults are caused by anaerobic bacteria,[149] reports of anaerobic endocarditis in children are exceedingly rare.[91,385,492,511]

Gram-Positive Bacilli

Infective endocarditis caused by *Corynebacterium* spp. is an unusual finding but may occur on normal or previously abnormal valves.[41,350] Both toxigenic[111] and nontoxigenic[195,479,493,532] strains of *C. diphtheriae* cause endocarditis in children, a finding demonstrating that the toxigenic and invasive properties of the organism are independent. Infection occurs most often on native valves and may be quite aggressive and lead to major vascular complications. *Listeria monocytogenes* endocarditis rarely occurs, has a high mortality rate, and, unlike other forms of listeriosis, usually is not associated with immunocompromised hosts.[35,71] It has not been associated with listeriosis in neonates. Fewer than 40 cases of *Lactobacillus* endocarditis have been reported.[194,231,514] Endocarditis caused by *Erysipelothrix rhusiopathiae* is found predominantly in

*References 115, 283, 318, 364, 517, 525.

*References 45, 86, 107, 229, 243, 320, 412.
†References 12, 148, 324, 368, 402, 429, 570.
‡References 57, 208, 223, 233, 417, 453, 483.

adults who are farmers or are exposed to farm animals or products.[189,206] Most cases of *Bacillus* endocarditis involve the tricuspid valve in intravenous drug users, but other patients have been affected, including those with prosthetic valves.[502] *Gemella morbillorum* (formerly *Streptococcus morbillorum*) is a gram-positive coccus that normally resides in the gastrointestinal tract and is a rare cause of endocarditis.[142,290,426]

Other Organisms

Many different bacteria, including *Acinetobacter*,[192] *Stenotrophomonas*,[447] *Nocardia*,[563] *Actinomyces*,[287] *Streptobacillus*,[455] and *Rothia*,[512] have been associated rarely with endocarditis.[59] Mycobacterial endocarditis is an exceedingly infrequent event.[170]

Infective endocarditis caused by *Coxiella burnetii*, the causative agent of Q fever, is well documented in northern Africa, Europe, and Australia.[4,58,291,304,359] Most cases are chronic (occurring over a 6- to 12-month period) and involve the aortic valve.[328] Clues to establishing the diagnosis include exposure to parturient cats or rabbits, massive splenomegaly, hypergammaglobulinemia, and thrombocytopenia.[415] The diagnosis usually is confirmed by measurement of antibodies against phase I and phase II antigens, but the organism has been isolated from leukocytes in a shell vial assay and has been demonstrated by immunohistologic techniques.[58,183] At least 20 well-documented cases of infective endocarditis caused by *Chlamydia psittaci* and *Chlamydophila pneumoniae* (formerly *Chlamydia pneumoniae*) have been reported.[216,253,336,488] Most patients have had preexisting heart disease and a subacute course.[329] *Mycoplasma* endocarditis is exceedingly rare.[119] *Legionella* has been implicated in several cases of prosthetic valve endocarditis.[538] *Bartonella quintana* and *B. henselae* have been identified as the cause of endocarditis in "culture-negative" cases.[106,122,217,242,496] Most described cases have been in immunocompetent individuals.[416] The diagnosis was established by serology, polymerase chain reaction, or special culture techniques.[28,150,160,434,559]

Although culture of bacteria remains the primary method for establishing the microbial cause of infective endocarditis, the number of organisms causing endocarditis that cannot be cultivated by standard culture methods is growing.[161,225] More recently, universal and species-specific primers have been designed to amplify bacterial DNA directly from resected valves. Among the organisms causing endocarditis identified by these methods are *Bartonella*, *Tropheryma whippelii*, *Coxiella*, *Mycoplasma*, *Haemophilus*, *Abiotrophia*, *Gemella*, *Cardiobacterium*, and *Streptococcus*.[174,188,225,312,427]

Fungi

Most cases of fungal endocarditis in children have been described as occurring after cardiovascular surgery and prolonged intravenous and antibiotic therapy.[134,140,353,534] More recently, cases have been reported in neonates[341] and after prosthetic valve placement.[388] The most common causative organism is *C. albicans*, although disease has been attributed to other *Candida* spp., including *C. krusei*, *C. parapsilosis*, *C. stellatoidea*, *C. tropicalis*, and *C. guilliermondii*.[424,465,484] Among intravenous drug users, *Candida* spp. other than *C. albicans* are more common causes of endocarditis.[454] The clinical manifestation usually is indolent and not specific, with symptoms occurring weeks to months before the diagnosis is established. Signs and symptoms caused by emboli to large vessels, especially those supplying the brain, kidney, spleen, and extremities, should alert the physician to the possible presence of fungal endocarditis. Large, friable vegetations occur frequently and can be detected by echocardiography.[509] Cutaneous and ocular manifestations of systemic *Candida* infection may be present.[54] The prognosis of *Candida* endocarditis is poor and is related to the propensity for septic emboli, the tendency for invasion into the myocardium, and the poor penetration of antifungal agents into the bulky vegetation. The diagnosis frequently is delayed by the tendency for negative or intermittently positive blood cultures to occur in this disease.[251] Surgical intervention usually is required.

Aspergillus spp., including *A. flavus*, *A. fumigatus*, *A. terreus*, and *A. niger*, are the second most frequent causes of fungal endocarditis, and such infections have been reported in 16 children.[31,32,390] Two thirds of these patients had underlying heart disease. *Aspergillus* endocarditis has been found in immunocompromised hosts with no previous cardiac problems.[583] The most common initial manifestations are fever and embolic phenomena, especially to the central nervous system.[560] Fewer than 25 cases have been diagnosed ante mortem, several by culture of peripheral emboli. Most cases occur after open heart surgery; the most likely source of the organism is airborne inoculation of the heart during the operation.[31,343] Surgical removal of all infected material is recommended, although only several children have been treated successfully. Other fungi that rarely cause endocarditis include *Histoplasma capsulatum*, *Coccidioides immitis*,[292] *Cryptococcus neoformans*, *Torulopsis glabrata*, *Trichosporon beigelii*,[269] and *Fusarium* spp.[198,226]

TREATMENT

In the preantibiotic era, infective endocarditis was a uniformly fatal disease. With the current improved methods of diagnosis and therapy, 80 to 90 percent of children with this disease can be expected to survive. Mortality rates are higher for acute staphylococcal infection, fungal endocarditis, and prosthetic valve endocarditis, although the tendency toward earlier surgical intervention for these entities may improve survival rates. The cornerstone of successful therapy is selection of antibiotics with specific activity against the causative organism. Better analysis of pharmacodynamic variables, such as bactericidal activity and the postantibiotic effects of various drugs, may assist in the selection of optimal therapeutic regimens.[95,275,578] Although persistent infection occasionally complicates treated endocarditis,[438] deterioration in cardiac function is the major cause of morbidity and mortality.

Several general principles provide the basis for the current recommendations for treatment of endocarditis.

Parenteral administration of antibiotics is preferred because erratic absorption of oral antibiotics, especially in infants, can lead to therapeutic failure. Although patient selection criteria for the use of outpatient parenteral antibiotic therapy for endocarditis in adults have been suggested, no data have been published about this practice for children.[10] Prolonged treatment, usually 4 to 6 weeks or longer, is necessary to sterilize the vegetations and to prevent relapse. Bacteriostatic antibiotics are not effective and lead to frequent relapses or failure to eradicate the infection, or both. Antibiotic combinations may produce a rapid bactericidal effect through synergistic mechanisms of action. When synergy exists, smaller doses of each drug may be used, thereby reducing toxic side effects. However, certain drug combinations can be antagonistic, and their use should be avoided.

Blood should be drawn for culture for several days to evaluate the effect of the antibiotics. Negative follow-up cultures do not guarantee the success of therapy, but persistent positive cultures usually require that a change or addition to the antibiotic regimen be made. Observation of the patient's clinical course is extremely important. When fever is present initially, the temperature often returns to normal within a few days after therapy is started. However, fever can persist for weeks in patients whose eventual outcome is good. Such patients must be monitored closely for cardiac arrhythmias and congestive heart failure, which may require intensive care observation and electrocardiographic monitoring. Evidence of major embolic phenomena must be sought diligently by physical examination.

Several laboratory tests may aid in monitoring therapy. In all cases of bacterial endocarditis, the minimal inhibitory concentration (MIC) and minimal bactericidal concentration (MBC) ideally are determined for the antibiotics being used because disk susceptibility testing may not be as reliable and is not quantitative. The role of monitoring the inhibitory and bactericidal activity of the patient's serum is highly controversial. The Schlichter test determines the maximal dilutions of a patient's serum that in vitro inhibit and kill an inoculum of the organism causing the endocarditis.[437] Standardization of this test is poor, with laboratories using variations in inoculum size, in composition of the broth, in timing of samples (at expected peak or trough antibiotic concentrations in serum), in methods of dilution, and in determining the bactericidal end point. In the rabbit endocarditis model, peak serum bactericidal titers greater than 1:8 correlate with therapeutic success.[69] A retrospective review of 17 reports of serum bactericidal activity in patients with endocarditis failed to show any correlation between titers greater than 1:8 and therapeutic success.[92] A prospective study suggested adjusting antibiotic doses to achieve peak titers of 1:64 or greater and trough titers of 1:32 or greater.[569] At present, no generally accepted recommendation can be made. In general, to attempt to achieve a peak serum bactericidal titer of at least 1:8 or greater seems reasonable if serious drug toxicity is not encountered. However, this level may not be attainable with certain organisms such as enterococci and gram-negative bacilli. Serum bactericidal testing may be particularly useful when synergistic combinations or less well-established antibiotic regimens are used or when response to therapy is suboptimal.[582]

TABLE 26-8 Suggested Intravenous Antibiotic Doses and Schedules for Infective Endocarditis in Children

Antibiotic	Daily Dose/kg	Divided Doses Every:
Aqueous crystalline penicillin G sodium	300,000 U	4-6 hr
Ampicillin sodium	300 mg	4-6 hr
Ampicillin-sulbactam	300 mg	4-6 hr
Cefazolin	100 mg	6-8 hr
Ceftriaxone	100 mg	12 hr
Ciprofloxacin	20-30 mg	12 hr
Doxycycline	2-4 mg	12 hr
Gentamicin sulfate	3 mg	8 hr or 24 hr
Imipenem/cilastatin	60-100 mg	6 hr
Linezolid	30 mg	8 hr
Meropenem	60 mg	8 hr
Nafcillin sodium	200 mg (max., 12 g)	4-6 hr
Oxacillin sodium	200 mg (max., 12 g)	4-6 hr
Rifampin	20 mg	8-12 hr

Little information is available concerning optimal antibiotic therapy for infective endocarditis in children; most treatment regimens are adapted from studies of adults with endocarditis.[25,579] In general, these regimens have been equally successful (and generally less toxic) in children. Recommended doses of the antibiotics commonly used are listed in Table 26-8.

After performing the initial evaluation of a patient with suspected infective endocarditis, the physician must make a clinical judgment about when to initiate therapy. If the findings are strongly indicative of the diagnosis or the child is very ill, treatment should be started as soon as blood has been drawn for culture. Initial empirical therapy depends on the clinical setting in which the tentative diagnosis is made. If the infection is subacute, a combination of penicillin G and an aminoglycoside usually is recommended for its activity against viridans streptococci, enterococci, and most gram-negative organisms. If *S. aureus* endocarditis is a strong consideration (acute manifestation, narcotic addicts), vancomycin and a penicillinase-resistant penicillin should be added to this regimen. Patients who recently have undergone cardiac surgery, especially prosthetic valve placement, are treated best with an aminoglycoside and vancomycin to "cover" for health care–associated infection caused by MRSA or CONS; some physicians add penicillin G to this regimen to improve activity against streptococci. When culture and susceptibility data are known, antibiotic therapy can be changed as needed.

Most strains of viridans streptococci, *S. pyogenes*, and nonenterococcal group D streptococci are exquisitely susceptible to penicillin, with an MIC of less than 0.2 μg/mL. However, 15 to 20 percent of viridans streptococci have an MIC of 0.2 μg/mL or greater and are defined arbitrarily as relatively resistant.[227] In addition, some strains (particularly *S. mutans* and *S. mitior*) demonstrate tolerance, that is, an MIC to penicillin of less than 0.1 μg/mL but an MBC that is more than 10-fold higher (1.25 to 50 μg/mL). Most strains of nutritionally dependent streptococci are tolerant to penicillin.[24] Clinical failure may occur in endocarditis caused by these tolerant organisms when penicillin alone is used for treatment.[9,227] However, except for nutritionally dependent streptococci, therapy for tolerant viridans streptococci generally should be the same as for susceptible strains.

Although most experts recommend that patients with endocarditis caused by relatively resistant streptococci be treated with high doses of penicillin combined with 2 to 4 weeks of an aminoglycoside, some authorities consider that penicillin alone usually is adequate therapy.[48,117,327] Synergy in vitro between penicillin or vancomycin and streptomycin or gentamicin can be demonstrated against virtually all penicillin-susceptible streptococci.[562] This observation correlates with a faster rate of eradication of bacteria from cardiac vegetations in the rabbit endocarditis model when synergistic combinations of antibiotics are used.[127,130] However, streptomycin is not synergistic for strains with high-level streptomycin resistance; gentamicin is the preferred second drug for these rare isolates.[136] In pediatric patients, gentamicin usually is substituted for streptomycin because of its lower toxicity.

Several regimens have been examined in adults with penicillin-susceptible viridans streptococcal native valve endocarditis (Table 26-9). A 2-week course of penicillin alone leads to an unacceptable relapse rate. However, a 2-week course of intramuscular procaine penicillin and streptomycin cured 99 percent of adults with penicillin-susceptible streptococcal endocarditis in one report.[580] These results are similar to those obtained with β-lactams alone for 4 weeks[263] or with penicillin for 4 weeks combined with streptomycin for the first 2 weeks. Gentamicin may be substituted for streptomycin. The 2-week penicillin-gentamicin regimen is the least expensive and is the preferred therapy in uncomplicated cases of penicillin-susceptible streptococcal endocarditis in young adults.[474] In general, the regimen of 4 weeks of penicillin alone is preferred for patients in renal failure or at high risk for developing aminoglycoside-induced ototoxicity. Vancomycin or ceftriaxone administered for 4 weeks can be used in patients with penicillin-susceptible viridans streptococcal endocarditis who have a penicillin allergy.[166,167,485,510] The regimen of 4 weeks of penicillin plus an initial 2 weeks of gentamicin is recommended in adults with a complicated course (symptoms for >3 months) or with infection caused by relatively penicillin-resistant organisms (Table 26-10). Most nutritionally

deficient streptococci are tolerant to penicillin. For patients with endocarditis caused by these organisms, a course of 4 to 6 weeks of penicillin with the addition of an aminoglycoside is recommended (Table 26-11).[25,579] In patients with streptococcal infection of prosthetic valves or other prosthetic materials, a 6-week regimen of penicillin usually supplemented with an aminoglycoside is recommended (Table 26-12). None of the regimens discussed has been evaluated specifically in children with endocarditis.

Most strains of enterococci have an MIC to penicillin of 0.4 μg/mL or greater and an MBC of 6.25 μg/mL or greater.[375] All β-lactam antibiotics are bacteriostatic against enterococci and cannot be used alone. However, plasmid-mediated β-lactamase production has been found in rare strains of *Enterococcus faecalis*. Ampicillin-sulbactam overcomes the enzyme production and may be effective as therapy.[529] Although therapy with penicillin alone is ineffective, the combination of penicillin and an aminoglycoside is synergistic and produces a bactericidal effect on most enterococcal strains. Unfortunately, 20 to 50 percent of enterococcal strains demonstrate very high resistance (MIC >2000 μg/mL) to streptomycin, and synergy between penicillin and streptomycin does not occur.[209,473] High-level resistance to gentamicin has been found in some isolates, and the incidence is increasing in certain locales.[133,311,403] When these isolates are encountered, all aminoglycosides should be tested because the organism may be susceptible to one while resistant to others.[567] Fortunately, these strains rarely cause endocarditis.[375] Although vancomycin-resistant enterococci have emerged as important nosocomial pathogens, they rarely cause endocarditis in children. Optimal therapy for these strains has not been established, but a combination of high-dose penicillin plus vancomycin and gentamicin may be effective in some cases.[66] Vancomycin-resistant enterococcal endocarditis has been treated successfully with oral linezolid.[11,16] The usual regimens for enterococcal endocarditis are listed in Tables 26-11 and 26-13.

Most isolates of *S. aureus* are resistant to penicillin, but endocarditis caused by penicillin-susceptible (MIC <0.1 μg/mL) isolates can be treated with this agent. In general, a semisynthetic penicillinase-resistant penicillin given for 6 weeks is the drug of choice (Table 26-14).[313,408,500] The addition of gentamicin to nafcillin produces an enhanced bactericidal effect in vitro and in experimental staphylococcal endocarditis in rabbits.[466] However, the value of this combination in patients has not been proved, and generally it is reserved for children with overwhelming infection. In penicillin-allergic patients or in those

with MRSA, vancomycin alone has been recommended, although treatment failures in children with endocarditis have been reported.[144,239,302] The addition of rifampin or the use of β-lactam drugs after desensitization is necessary in some cases.[34,369] Ciprofloxacin has been used, but

treatment failures have occurred because of the emergence of resistance.[373,526] Vancomycin for at least 6 weeks, plus the addition of gentamicin for the first 2 weeks, is often recommended for the treatment of endocarditis caused by MRSA, although clinical trial data are not available. Daptomycin and linezolid also have been used successfully to treat endocarditis caused by MRSA.[163,358] Nosocomial infections with *S. epidermidis* usually are treated with vancomycin because of the high incidence of methicillin resistance among these isolates. The addition of rifampin and gentamicin to either nafcillin or vancomycin may increase bactericidal activity and is recommended in cases of prosthetic valve endocarditis secondary to any staphylococci (see Table 26-13).[25]

Therapy for endocarditis caused by gram-negative organisms must be individualized in accordance with in vitro susceptibility studies. A regimen of 6 to 8 weeks of combination therapy with two or more drugs may be required, especially with endocarditis caused by *Klebsiella* or *Pseudomonas*.[156,407] Surgical intervention frequently is necessary, especially for infection of the mitral or aortic valves. Endocarditis caused by *Haemophilus* and other fastidious gram-negative organisms usually is responsive to ampicillin, ceftriaxone, or ciprofloxacin alone,[25] but the addition of an aminoglycoside may improve the outcome (Table 26-15).[25,86] Anaerobic bacilli generally are susceptible to penicillin, but infection caused by resistant *Bacteroides fragilis* is treated best by combinations including metronidazole, ticarcillin-clavulanate, piperacillin-tazobactam, imipenem, or meropenem.

Survival rates of only 10 to 20 percent in patients with fungal endocarditis are related to the poor ability of currently available antifungal agents to sterilize the vegetations. Only rare cures with medical therapy alone have been reported.[465] Most investigators contend that early surgical intervention is mandatory in every patient who has conclusive evidence of intracardiac fungal infection.[504,546,547] Eradication of fungal prosthetic valve endocarditis has been reported rarely, even when surgery was performed.[182]

Although a prolonged course of antifungal therapy before surgery does not improve the outcome, chemotherapy should be given in conjunction with operative treatment. The drug of choice is usually amphotericin B or liposomal amphotericin. This antibiotic may be either fungistatic or fungicidal, depending on the infecting organism. Even though the toxicity of amphotericin B appears to be less severe in children than in adults, side effects that may necessitate alterations in the usual regimen may occur and include fever, chills, phlebitis, anemia, hypocalcemia, renal tubular acidosis, nephrotoxicity, and thrombocytopenia. The optimal dosage of amphotericin B is unknown; total doses of 20 to 50 mg/kg commonly are used. 5-Fluorocytosine[347] may act synergistically with amphotericin B against many strains of fungi, but their roles in fungal endocarditis are unproven. Fluconazole is less effective than is amphotericin B for the prophylaxis or treatment of experimental *Candida* endocarditis,[581] but it has been used successfully in a few patients.[97,554] Some newer antifungal agents, such as caspofungin, have been used successfully to treat fungal endocarditis, but the reported experience in children is limited.[522]

Treatment of culture-negative endocarditis is problematic.[30] In general, the same criteria used to choose empirical therapy for infective endocarditis can be followed. Antibiotics usually are continued for 6 weeks, and ongoing surveillance for an etiologic agent must be performed. In 52 adults with culture-negative endocarditis, survival correlated with the initial clinical response to antibiotics; most deaths were caused by systemic emboli or congestive heart failure.[414]

Surgery has become a valuable adjunct to medical therapy in the management of infective endocarditis.[33,398,413,421,462] The general trend has been for surgical intervention to be undertaken earlier and more frequently to prevent complications of endocarditis and lower mortality.[224,453,587] Several echocardiographic findings suggest a possible need for surgical intervention (Table 26-16).[33,155] Among the generally accepted indications for surgical intervention during active endocarditis are (1) refractory congestive heart failure,[352,536,577] (2) uncontrolled infection,[329] (3) more than one serious embolic episode, (4) fungal endocarditis, (5) most cases of prosthetic valve endocarditis,* and (6) local suppurative complications including perivalvular or myocardial abscess with conduction system abnormalities.† The usual indication for surgical intervention is congestive heart failure in left-sided lesions and persistent infection in right-sided disease.[112,556] Among children with endocarditis after cardiac surgery, repair or takedown of infected graft material commonly is the reason for surgery.[88,394] Recent studies have demonstrated that preservation of the child's native valve is frequently possible despite advanced clinical disease.[113,213,214,259] In general, operative mortality is low even if surgery is performed during the active infection.[372,387] The hemodynamic status of the patient, rather than the activity of the infection, is the critical factor in determining the timing of cardiac surgery or valve replacement.[3,260] The aortic valve is the site most often requiring surgical intervention.[366,423,540] Treatment with recombinant tissue plasminogen activator has been used successfully in some cases of endocarditis when surgery could not be performed safely.[196,303]

PREVENTION

Accepted medical practice has been to give prophylactic antibiotics to susceptible patients in an attempt to prevent infective endocarditis.[125,268,491] The rationale for such treatment is based on studies indicating that antibiotics can reduce the incidence of bacteremia after various procedures in humans[139] and can prevent experimental endocarditis in animals.[410] However, no controlled trials have documented the efficacy of endocarditis prophylaxis in humans.[551] Prevention of bacterial infection is most likely to be successful and cost effective when a single antibiotic is directed against a single pathogen and when the disease occurs with high frequency in the absence of prophylaxis. Prevention of endocarditis has not met these ideals because various drugs have been used against numerous organisms, and the disease rarely occurs even if prophylaxis is not given.[123] Fewer than 10 percent of all endocarditis cases can be attributed to bacteremia caused by previous medical, surgical, or dental procedures.[550] Many cases of prophylaxis failure have been reported,[128] but only 12 percent of such patients received antibiotic regimens recommended by the American Heart Association. For reasons that are not clear, mitral valve prolapse was the condition associated most frequently with failure of prophylaxis.

The most common errors in attempted prevention of endocarditis included inadequate medical histories taken

by dentists and other health care professionals to identify high-risk patients, initiation of prophylactic antibiotics too early, continuation of preventive therapy too long, the use of low-dose antibiotics, lack of prophylaxis for minor dental procedures, and confusion between prevention of rheumatic fever and prevention of infective endocarditis.[158,201,207] Several studies have shown that adult patients at risk for development of infective endocarditis often have inadequate knowledge of their cardiac lesion, endocarditis, and recommended prophylaxis.[74,281,552] Several studies demonstrated that the parents of children with heart defects have a low level of knowledge about the importance of good oral health in preventing endocarditis.[26,109,199,386,431] Another study cast doubt on the cost-effectiveness of endocarditis prophylaxis for urinary catheterization in children.[73]

The American Heart Association published new and radically different guidelines for the prevention of infective endocarditis in 2007.[576] These new guidelines eliminated many of the procedures for which prophylaxis previously was recommended.[99] It is now recommended that prophylaxis be undertaken for all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. Prophylaxis also can be considered for procedures on the respiratory tract or infected skin, skin structures, or musculoskeletal tissue. Prophylaxis no longer is recommended for gastrointestinal or genitourinary tract procedures. In addition, the number of heart lesions for which prophylaxis is recommended has been reduced to only those with the highest risk for endocarditis (Table 26-17).[576] Finally, the specific regimens for prophylaxis have been changed and simplified to encourage more judicious use (Table 26-18). Although some experts have expressed doubt about the validity of these newer recommendations,[487] there is no evidence that the release of these guidelines has been associated with a significant change in admissions for infective endocarditis.[400]

Immunization against bacteria that commonly cause endocarditis (e.g., viridans streptococci) has been proposed, but this approach remains a theoretical possibility.[19]

TABLE 26-17 Heart Conditions with the Highest Risk for Adverse Outcome from Endocarditis for Which Prophylaxis with Dental Procedures Is Recommended

- Prosthetic heart valve
- Previous infective endocarditis
- Congenital heart disease
  - Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or catheter, during the first 6 months after the procedure
  - Repaired congenital heart disease with residual defects at or adjacent to the site of a prosthetic patch or device
- Cardiac transplantation recipients who develop cardiac valvulopathy

CHAPTER 27

Infectious Pericarditis

Sheldon L. Kaplan

Purulent pericarditis generally refers to bacterial infection of the pericardium. Inflammation of the pericardium may result from numerous nonbacterial microorganisms, however, or may occur with a variety of noninfectious illnesses (Table 27-1). Regardless of the cause of pericarditis, the responses of the pericardium are limited to acute inflammation, effusion with or without tamponade, and fibrosis with or without constriction.[20] Because untreated purulent pericarditis is rapidly fatal, suspecting the disease early and approaching the diagnosis aggressively are important.

ANATOMY AND FUNCTION

The pericardium is composed of two loosely approximated layers: visceral and parietal. The visceral pericardium is composed of mesothelial tissue, which closely follows the contour of the heart and extends for a short distance beyond the atria and ventricles to the great vessels. The outer parietal pericardium is a more fibrous structure, composed of layers of collagen interlaced with elastic fibers. The pericardial sac is attached to the diaphragm below; to the sternum in front; and to the thoracic vertebrae, esophagus, and aorta posteriorly. It is surrounded by the lungs on either side and is related closely to the main bronchi and the mediastinal lymph nodes. The phrenic and vagus nerves supply a network of pain fibers to the parietal pericardium.

The dynamics of the pericardial fluid are poorly understood. The pericardial membrane is active in the transfer of water, electrolytes, and small molecules. Molecules of large molecular weight are absorbed poorly from the pericardial space because lymphatic channels are sparse, and drainage must occur primarily through the epicardial capillaries.[73]

Ainger[1] summarized the function of the pericardium as follows: prevention of overdistention of the heart, protection of the heart from infection and adhesions, maintenance of the heart within a fixed geometric position within the chest, and regulation of the interaction between the stroke volumes of the two ventricles.

BACTERIAL PERICARDITIS

Population and Incidence

Although purulent pericarditis is not a common infection in pediatric patients, it is an important one to recognize because of its life-threatening nature. In an extensive early review of the literature on purulent pericarditis, half of 425 cases occurred in children younger than 13 years of age.[6] In a review of 162 reported children with pericarditis from 1950 to 1977, 67 percent of the children were 48 months old or younger.[31] From 1962 to 1974, 67 cases were recognized at St. Louis Children's Hospital (Table 27-2).[93] During this 12-year period, pericardial disease of all causes occurred in approximately 1 of every 850 hospital admissions.[93] Twelve (18%) of these children had purulent pericarditis.

Most cases in younger children are infectious. Acute pericarditis was found in 20 children between 1987 and 1997 in a hospital in Iran.[82] The causes of pericarditis were bacterial in eight (40%), collagen vascular disease in six (30%), viral in four (20%), and secondary to mediastinal mass invasion in two (10%). In another series from Turkey, 18 children with purulent pericarditis were encountered from 1990 to 2000.[10] At the Boston Children's Hospital, fewer than 10 patients seen among more than 1700 patients in consultation by the pediatric cardiologists had pericarditis during the period July 1, 2001, to June 30, 2002.[36] Over a 21-year period, 31 children with an inflammatory large pericardial effusion requiring drainage were admitted to one tertiary care children's hospital; 12 of the effusions were caused by bacterial infections.[70] Although rare, purulent pericarditis also can occur in neonates.[57] In most series, a marked male predominance has been noted.

Etiology

Primary purulent pericarditis is a rare disease; it accounted for only 7 of 50 cases of pericarditis reported by Gersony and McCracken.[37] The disease is associated most often with infection from another site, with hematogenous or direct spread to the pericardium. Feldman[31] reviewed all cases of bacterial pericarditis reported in the English language literature from 1950 to 1977. Bacteria were isolated in 146 (90%) of 162 cases. No other infection was found in 10 patients. The most common concomitant site involved was the lung, especially for *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*. When septic arthritis, osteomyelitis, or skin infections were found, *S. aureus* usually was the cause of pericarditis. *Neisseria meningitidis* and *H. influenzae* most often were responsible for concomitant meningitis and pericarditis.

Before the introduction of antibiotics, pneumococcal and streptococcal organisms were the most frequent causes of purulent pericarditis in children. Most cases

TABLE 27-1 Causes of Pericarditis

Idiopathic
Benign
Recurrent

Infectious
Purulent
Bacterial—*Staphylococcus aureus, Haemophilus influenzae,* streptococci, *Neisseria meningitidis, Streptococcus pneumoniae,* anaerobes, *Francisella tularensis, Salmonella,* enteric bacilli, *Pseudomonas, Listeria, Neisseria gonorrhoeae, Actinomyces, Nocardia*
Tuberculosis
Fungal—*Histoplasma, Coccidioides, Aspergillus, Candida, Blastomyces, Cryptococcus*

Viral
Coxsackieviruses B
Other—influenza A and B, mumps, echoviruses, adenoviruses, Epstein-Barr virus, hepatitis, measles, human immunodeficiency virus, cytomegalovirus

Other
Rickettsial—typhus, Q fever
Mycoplasmal—*Mycoplasma pneumoniae*
Parasitic—*Entamoeba histolytica, Echinococcus*
Spirochetal—syphilis, leptospirosis
Chlamydial—psittacosis
Protozoal—toxoplasmosis

Noninfectious
Postpericardiotomy syndrome
Kawasaki disease
Rheumatic fever
Connective tissue disorders—juvenile rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, periarteritis nodosa
Trauma—blunt or penetrating
Metabolic—uremia, myxedema
Hypersensitivity—serum sickness, pulmonary infiltrates with eosinophilia, Stevens-Johnson syndrome, drugs (hydralazine, procainamide, chemotherapy)
Neoplasm—leukemia, metastatic
Post irradiation

TABLE 27-2 Pericarditis in Children, 1962 to 1974 (St. Louis Children's Hospital)*

Etiology	No. Patients
Unknown	28
Purulent	12
Juvenile rheumatoid arthritis	9
Acute rheumatic fever	8
Uremia	5
Viral	2
Blunt chest trauma	2
Dermatomyositis	1

*Patients with postpericardiotomy pericarditis and patients with small exclusions at autopsy were excluded from consideration.
From Strauss AW, Santa-Maria M, Goldring D. Constrictive pericarditis in children. *Am J Dis Child* 1975;**129**:822–6.

were associated with pulmonary infections. Nearly half of patients with streptococcal pericarditis had associated postinfluenzal pneumonia. Hemolytic streptococci were isolated most often; 10 percent were nonhemolytic streptococci, and 5 percent were viridans streptococci. Kauffman and colleagues[59] reviewed 113 cases of pneumococcal pericarditis reported since 1900. Preceding pneumonia was present in 93 percent, and empyema was present in 66 percent. Pericarditis was thought to be a late event resulting from delay in administering appropriate therapy for pneumonia.

S. aureus is the organism most commonly responsible for purulent pericarditis in children.[5,31,37,49,82] Most cases are the result of hematogenous seeding of the pericardium from staphylococcal pneumonia with empyema, acute osteomyelitis, or soft tissue abscesses. Among 117 children with *S. aureus* pneumonia at Texas Children's Hospital, 13 children had an echocardiogram; 1 had a large pericardial effusion.[14] Occasionally, the pericardium is infected during the course of staphylococcal endocarditis. *S. aureus* is the most frequently recovered organism when purulent pericarditis develops within 3 months after the patient has undergone open heart surgery. The clinical course of acute staphylococcal pericarditis is dominated by severe toxemia. In addition to the necrotizing infection produced by *S. aureus*, the organism may release exotoxins, which produce shock and contribute to the high mortality. Community-associated methicillin-resistant *S. aureus* isolates have been recovered from some patients with acute pericarditis.[52]

S. aureus was isolated from 73 percent of infants who died of purulent pericarditis in the series reported by Gersony and McCracken.[37] It was responsible for 50 percent of cases in children 1 to 4 years old in the review by Feldman.[31] In 7 patients younger than 1 month of age, *S. aureus* was isolated from 4. This finding is corroborated in literature from other countries.[21,54,82] Thebaud and colleagues[97] reported 19 patients with purulent pericarditis in a children's hospital in Paris between 1979 and 1994. The mean age of the children was 3 years (range, 3 months to 10 years). The organisms isolated were *S. aureus* (three cases), *H. influenzae* (four cases), group A streptococci (three cases), *S. pneumoniae* (three cases), and *N. meningitidis* (one case). Concomitant infections included pneumonia (six cases), osteomyelitis (three cases), cellulitis (one case), and sinusitis (one case). In the series from Turkey, *S. aureus* was isolated from 5 patients and *S. pneumoniae* was isolated from 1 patient.[10] *S. aureus* pericarditis as a complication of varicella has been reported in several children.[8] *S. aureus* has also caused pericarditis associated with disseminated infection in a child with IRAK-4 deficiency.[19]

In the prevaccine era, the second most frequently encountered organism was *H. influenzae* type b.[7] It was responsible for 22 percent (35 of 163) of the cases in Feldman's review.[31] A single site of coexisting infection, the lung, was identified in 16 of the 35 cases. Meningitis as a single other site of infection was found in 5 of 35 patients, and multiple involvement was found in 7 of 35.[31] Echeverria and colleagues[26] summarized 33 cases from the literature. Pulmonary infiltrates and empyema were seen in 64 percent of patients. Because *H. influenzae* type

b conjugate vaccine has been given routinely to young infants in developed countries, this organism has been eliminated as a cause of invasive infections, including pericarditis.

Pneumococcal, streptococcal, and meningococcal pericarditis have diminished in frequency since the introduction of penicillin.[6] Go and coworkers[38] summarized the 15 reported cases of pneumococcal pericarditis from 1980 to 1998. One was a child. Only 4 cases did not have an underlying risk factor. In a surveillance study of invasive pneumococcal infections in eight pediatric hospitals, only 3 cases of pericarditis have been observed in more than 2500 cases of systemic pneumococcal infection during the 6-year period of 1993 through 1999.[58] Nevertheless, *S. pneumoniae* remains an important, although rare, cause of acute bacterial pericarditis.[30] The routine administration of the pneumococcal conjugate vaccine to young children has likely resulted in *S. pneumoniae* being an even less common cause of acute pericarditis.

Pericardial involvement occurs in approximately 5 percent of young adults with meningococcemia.[23,44] The clinical course generally is milder than that observed with other types of purulent pericarditis. Pericardial involvement rarely is detected at the time of hospital admission. Pericarditis became apparent by the third day in 13 of 17 patients reported by Dixon and Sanford.[23] In some patients, it did not occur until late in the course of therapy. Whether this late-onset pericardial effusion is a part of the meningococcal infection or is related to immune complexes is unclear.[23,76,87] Primary meningococcal pericarditis that occurs without clinical evidence of meningococcemia, meningitis, or any other focal infection has been reported in 16 patients, including 6 children 18 years old or younger (range, 2 to 18 years).[3] Meningococcal serotype C was identified in 11 (79%) of 14 cases for which the serotype was known. Cardiac tamponade developed in 88 percent of the patients. Pericarditis also has been reported in 2 children with W135 meningococcal infection.[27]

Occasionally, other microorganisms cause acute purulent pericarditis. Feldman[31] reported that 11 (8%) of 146 cases of pericarditis in children were caused by *Pseudomonas aeruginosa*. *P. aeruginosa* caused pericarditis in an immunocompetent adult with cystic fibrosis.[2] Pericarditis can occur with pneumonic tularemia, salmonellosis, sepsis from enteric bacilli, listeriosis, and disseminated gonococcal disease.[6] Anaerobic bacteria should be suspected when pericarditis develops in association with lung abscess, intra-abdominal infection including ruptured appendicitis,[95] or a penetrating wound. Callanan and colleagues[12] reported the rapid development of constrictive pericarditis after purulent pericarditis caused by anaerobic streptococcal infection. The child had a history of blunt trauma to the chest with no evidence of a penetrating wound 3 weeks before cardiac tamponade developed. The incidence of anaerobic infection may be underestimated because of improper handling of specimens for culture.[31] Prolonged symptoms related to pericarditis can be associated with *Mycoplasma pneumoniae* infection.[28]

Mycobacterium tuberculosis, previously a common cause of acute pericarditis in the United States,[5] now is responsible more often for chronic pericardial disease. This infection is a complication of miliary tuberculosis and rarely a primary infection. In the series of 2500 children with tuberculosis reported by Lincoln and Savell,[66] pericarditis was diagnosed in 0.4 percent and found at necropsy in 5 percent of patients. A review of 100 cases of tuberculous pericarditis in South African blacks by Desai[22] revealed a marked male predominance (72%). The duration of symptoms, consisting of cough and peripheral edema, in most patients was 0 to 120 days. Most patients were febrile and had congestive heart failure. Generalized lymphadenopathy occurred in nearly 30 percent of patients, pulsus paradoxus occurred in 50 percent, and a friction rub was audible in 25 percent. Of the 52 patients who had pericardiocentesis, 40 percent yielded fluid, but none was positive for acid-fast bacilli. Pericardial effusion was shown in 82 patients, 16 of whom died of tamponade and another 16 of whom developed constricting pericarditis.

The four stages of tuberculous pericarditis have been described as dry, effusive, absorptive, and constrictive.[78] Granulomas usually are found in the dry stage and heal with no sequelae. The effusive stage occurs commonly with tuberculous lymphadenitis, and 15 to 200 mL of fluid usually accumulates in the pericardial space. The absorptive stage is characterized by thickening of the pericardium with fibrin deposition. Further fibrin deposition and calcification occur during the constrictive phase. The disease may progress through all stages or remain in one stage.

Latent infection in the mediastinal lymph nodes with spread directly into the pericardium is thought to be the mode of involvement with *M. tuberculosis*.[78] The lymph nodes at the tracheal bifurcation often are the source.

Histoplasma pericarditis generally occurs with pulmonary, rather than disseminated, disease.[80] Coccidioidomycosis[16] and, rarely, blastomycosis[45] also may cause pericardial disease. Other pathogenic fungi include *Aspergillus* and *Candida*. These fungi are more serious considerations in patients who are immunosuppressed, have serious burns, or are receiving long-term, broad-spectrum antibiotics after undergoing cardiac surgery.[84]

Finally, several parasites such as *Trypanosoma cruzi* and *Toxoplasma gondii* can attack the pericardium.[46]

Pathology and Pathogenesis

Pericarditis begins with fine deposits of fibrin adjacent to the great vessels; it causes the pericardial membrane to lose its smoothness and translucency. Numerous granulocytes may extend into the myocardium.[40]

Bacterial pericarditis most commonly results from direct extension of infection from involved lung and pleura. Pulmonary infections may spread to the pericardium through the bronchial circulation.[43] Pericarditis also can develop through hematogenous dissemination from infection elsewhere, and it also may be the result of an immunologically induced response to a primary infection.

As pericardial fluid accumulates, intrapericardial pressure increases. The rate of increase is a function of the speed of accumulation and the compliance of the

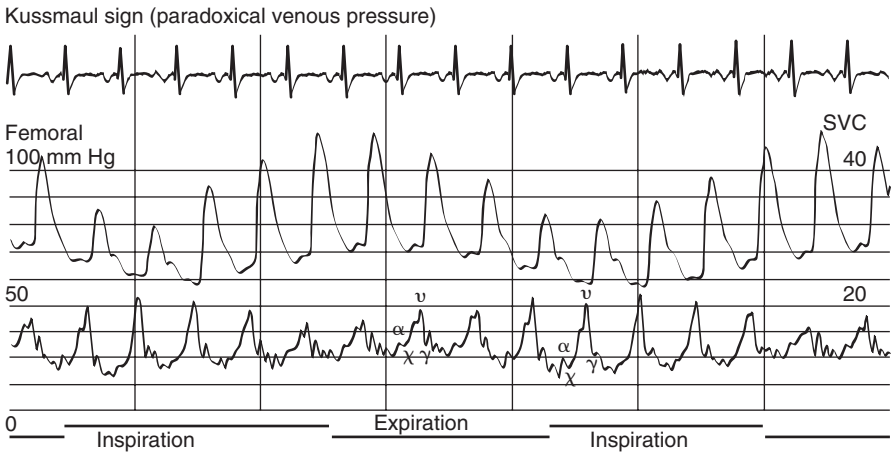

FIGURE 27-1 ■ Simultaneous recording of right atrial and femoral artery pressures. Notice the increased V wave and exaggerated decrease in the femoral artery pulse with inspiration.

pericardium. With slow accumulation of fluid, large volumes can be accommodated because of the gradual expansion of the parietal pericardium. As the compliance of the pericardium reaches its maximum, however, further accumulation of even small volumes of fluid results in an abrupt increase in intrapericardial pressure. If pericardial fluid accumulates at a rapid rate, marked elevation in intrapericardial pressure may occur with much smaller volumes of fluid. In a small child, 100 mL can cause severe tamponade, whereas 3 L may accumulate slowly in an older child and not result in tamponade.[1]

The most significant hemodynamic effect of pericardial effusion is restriction of ventricular filling. Ventricular end-diastolic, atrial, and venous pressures increase on the right and left sides of the heart equally. When restriction of ventricular filling becomes more pronounced, the ventricular stroke volume and cardiac output decrease. In an attempt to maintain cardiac output, tachycardia and peripheral vasoconstriction occur. Systemic arterial blood pressure and pulse pressure are reduced markedly. Tamponade occurs when these compensatory mechanisms fail to maintain adequate cardiac output.

Clinical Manifestations

A diagnosis of purulent pericarditis should be suspected in any patient with septicemia who develops cardiomegaly. The classic signs and symptoms of pericarditis are precordial pain, pericardial friction rub, evidence of cardiac fluid, and muffled heart sounds.[15] Chest pain is not a common symptom, especially in small children; the reported rates vary from 15 to 80 percent.* However, in one study focusing on 22 children (ages 6 to 17 years old) who presented to an emergency center and ultimately were found to have acute pericarditis, 95 percent had chest pain.[81] Acute abdominal symptoms may be the presenting complaints of some children.[24]

The most common symptoms and signs of pericarditis are fever, tachypnea, and tachycardia, which also are presenting features of associated systemic infection. If the cardiac shadow is radiographically enlarged, with or without a friction rub, and the tachypnea and tachycardia are out of proportion to the fever, myocardial dysfunction or pericarditis should be suspected.

An evanescent or ubiquitous rub may be detected. The typical sound of a rub is that of a high-frequency murmur,[79] which may have a to-and-fro or triphasic pattern but may not have any correlation with the cardiac cycle.[32] Frequently, the rub is heard better with the patient leaning forward or kneeling.[32] A rub may be differentiated from a murmur by pressing the diaphragm of the stethoscope firmly against the chest wall; this pressure amplifies the rub, and the typical scratchy quality becomes more apparent as the examiner opposes the visceral and parietal pericardium by compression of the chest. Rubs have been known to increase with inspiration.[92] Although a rub is less likely to be heard in the presence of a large effusion, it still may exist.[32] The heart sounds usually are muffled, and the palpable ventricular impulse generally is diminished. Both findings may be present in congestive heart failure, but they may be absent with tamponade.

Cardiac tamponade may be an early complication of pericarditis associated with a systemic infection. Cardiac tamponade means that there is compression of the heart by a tense pericardial sac, usually full of fluid, resulting in a decrease in venous return to the cardiac chambers and a decrease in cardiac output. During inspiration, the intrathoracic pressure decreases and venous return to the venae cavae increases. The tense pericardial sac limits the amount of blood that can enter the right atrium because of diastolic compression; a paradoxical increase in jugular venous pressure occurs during inspiration (i.e., Kussmaul sign) (Fig. 27-1).[61]

During inspiration, a small decrease in systolic blood pressure and cardiac output normally occurs and is caused by an increase in pulmonary venous capacitance. It is exaggerated with pericardial tamponade (>10 mm Hg decrease in blood pressure) because of the restricted inflow into the cardiac chambers. This clinical sign has been called *paradoxical pulse*, but it actually is an exaggeration of the normal respiratory cycle (Fig. 27-2).[39]

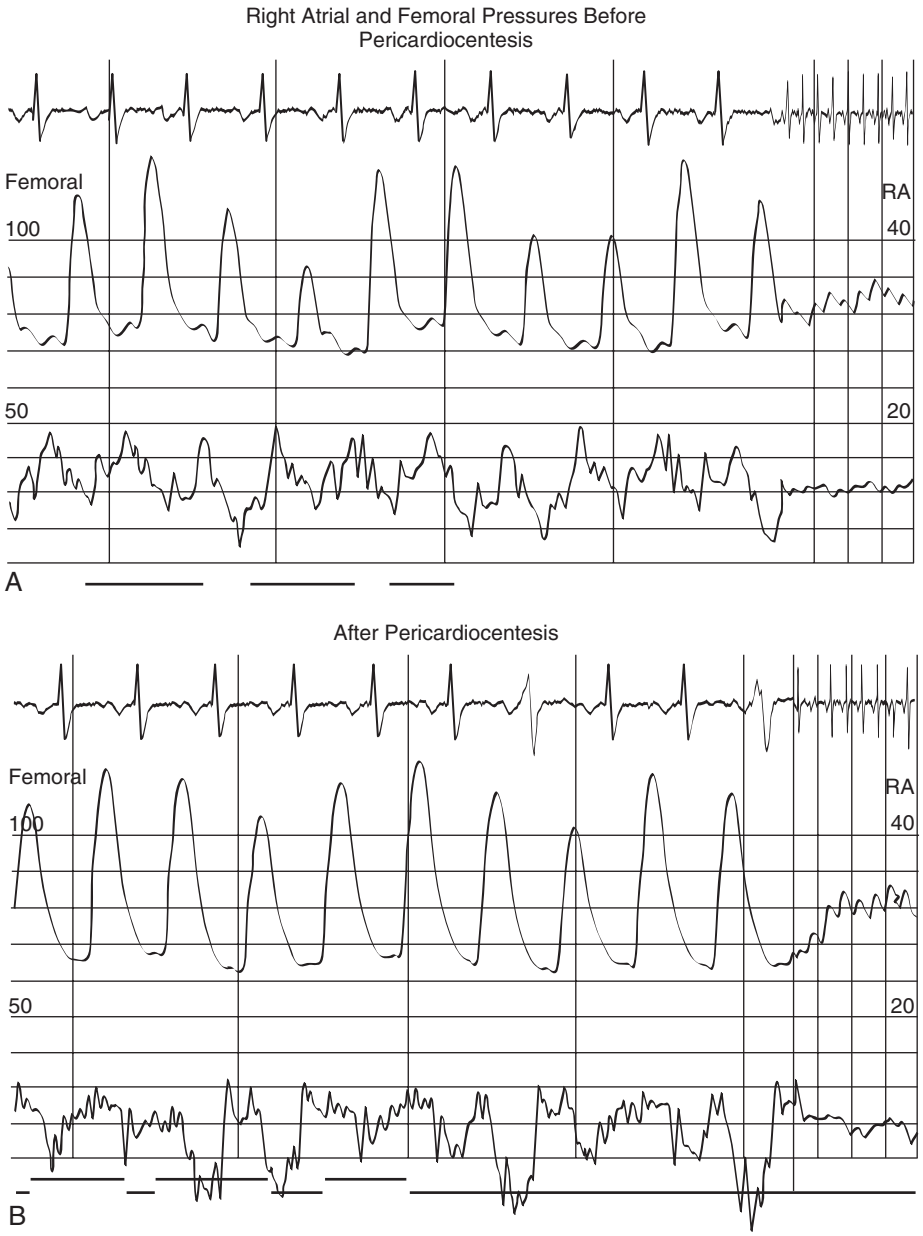

FIGURE 27-2 ■ Recordings of femoral artery and right atrial pressures before **(A)** and after **(B)** pericardiocentesis. **A,** There is an exaggerated decrease in the fall of femoral artery pressure with inspiration and a sustained increase in right atrial pressure. **B,** The recording shows a more normal variation of femoral pressure and a lower right atrial pressure.

Diagnosis

The radiographic appearance of a rapidly increasing cardiothoracic ratio without increasing pulmonary vascular markings is more suggestive of pericardial effusion than of congestive heart failure caused by myocardial dysfunction (Fig. 27-3). Fluoroscopy alone generally is of little value; myocardial dysfunction and pericarditis can impair cardiac contractility.

The size of the pericardial shadow does not indicate the severity of hemodynamic effects. It is a function of the rapidity of accumulation and the volume of pericardial fluid. When acute infection results in sudden cardiac tamponade, the heart size may be normal. A large, globular heart shadow with no evidence of increased pulmonary vasculature, particularly in a patient who has signs of right-sided heart failure, is strong evidence for pericardial disease. The lack of pulmonary overcirculation helps to distinguish this condition from myocarditis; however, determining whether pulmonary infiltrates also exist may be difficult.

A plain lateral chest radiograph may show findings consistent with a pericardial effusion.[63] Separation of more than 2 mm between the anterior mediastinal and subepithelial "fat stripes" suggests an effusion. Obliteration of the retrosternal space without evidence of thymic or right ventricular enlargement also indicates pericarditis.

The extent of electrocardiographic abnormalities may be explained by the amount of pericardial effusion and

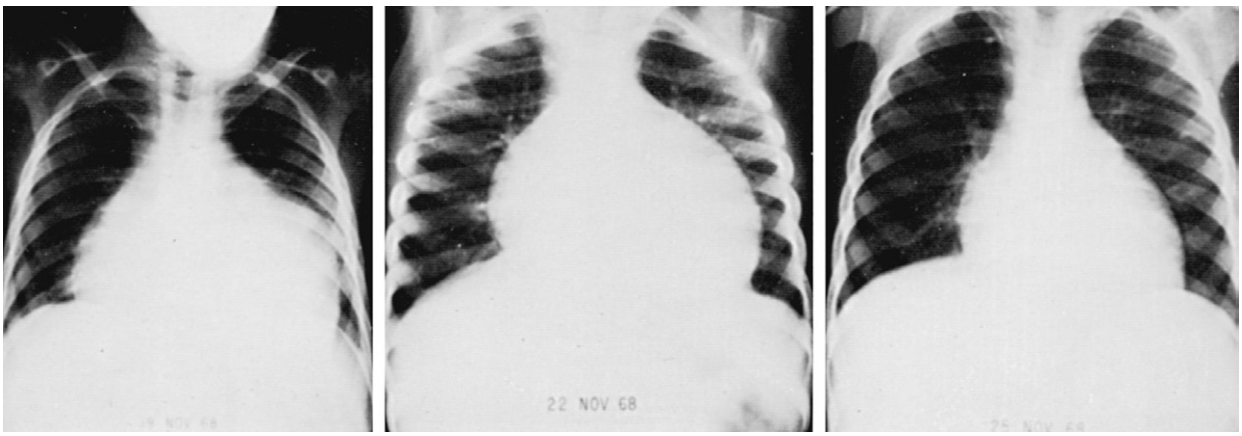

FIGURE 27-3 ■ In a patient with pericarditis, the first two radiographs show an enlarged cardiac shadow without an increase in pulmonary vascular markings. The third radiograph shows a marked decrease in apparent heart size after pericardiocentesis.

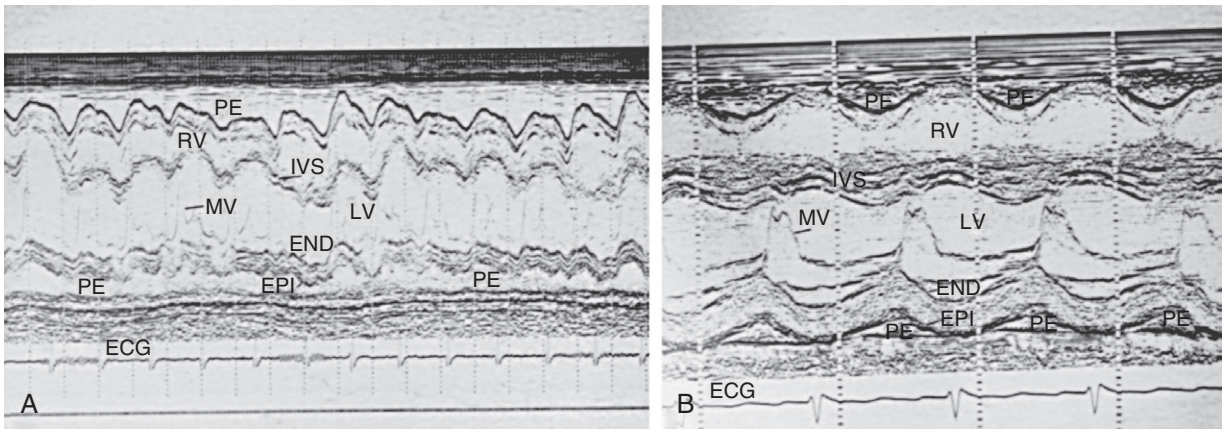

FIGURE 27-4 ■ Serial echocardiograms of a child before pericardiocentesis **(A)** and after pericardiocentesis **(B)**. **A,** Note the large effusion anteriorly and posteriorly with the "swinging" movement of the septum and anterior and posterior walls. **B,** The heart movement is normal, and there remains only a small effusion anteriorly and posteriorly. *ECG,* electrocardiogram; *END,* endocardium; *EPI,* epicardium; *IVS,* interventricular septum; *LV,* left ventricle; *MV,* mitral valve; *PE,* pericardial effusion; *RV,* right ventricle.

the presence of superficial myocardial injury or myocarditis. Pericardial effusion gives rise to low-voltage QRS complexes as a result of the damping effect of pericardial fluid between the chest wall and the myocardium. Accumulation of fluid and fibrin under pressure also may produce an injury pattern manifested by ST-segment deviation. More than 90 percent of patients have elevation of the ST segment, which occurs most frequently in leads I, II, V_5, and V_6. Widespread T-wave inversion indicative of epicarditis may be seen in the same leads in which ST-segment elevation occurs.

Spodick[90] described four stages of electrocardiographic changes in acute pericarditis. In stage I, ST-segment elevation is pronounced and the PR segment may be depressed. In stage II, the ST segment begins to return to the isoelectric line, the amplitude of the T wave diminishes, and the PR segment is depressed. By stage III, the ST segment has returned to the isoelectric line, and the T-wave inversion occurs. An incompletely inverted T wave (i.e., a diphasic wave or an upright T wave with a notched summit) sometimes is observed. In stage IV, these changes may resolve completely. T-wave abnormalities may persist for life, however, and do not indicate active disease.

Electrical alternans is seen in a large pericardial effusion. Electrical alternans refers to the alternation in electric amplitude of the T wave and the QRS complex with each cardiac cycle. It is thought to result from the rotational and pendular motion of the heart suspended in pericardial fluid.

Deviations from classic patterns occasionally occur, and single electrocardiographic changes are common findings. All 12 children reported by Okoroma and colleagues[77] had ST-segment elevation, whereas only 3 had concomitant low voltage.

Although many textbooks cite the frequent occurrence of dysrhythmias with pericarditis, these occurrences are unusual in the absence of coexisting heart disease. In one study, 20 of 49 patients with acute pericarditis had no underlying heart disease.[91] Seven patients had no dysrhythmias documented on 24-hour Holter monitoring, and 10 of 20 had infrequent single ectopic beats. Only 3 patients had supraventricular tachycardia.

M-mode echocardiography is the most sensitive method for diagnosing significant pericardial effusion (Fig. 27-4).[42,50] With a small to moderate effusion, only a "fluid space" is seen posteriorly (see Fig. 27-4B). With a larger effusion, fluid is seen anteriorly and posteriorly

and the septal motion becomes grossly abnormal. The heart may give the appearance of freely swinging (see Fig. 27-4A). Newer echocardiographic techniques, such as two-dimensional sector scanning, are not more useful than the conventional M-mode.

Friedland and colleagues[34] prospectively performed transthoracic two-dimensional echocardiography in 36 children with staphylococcal bacteremia; 89 percent had at least one suspected focus of infection, and 19 had community-acquired infections. Vegetations were detected in 4 children without clinical manifestations of endocarditis. Two other children, including one without suggestive clinical features, had significant pericarditis detected. The researchers concluded that echocardiography should be considered for children with bacteremia caused by *S. aureus*, even when an obvious noncardiac source of infection exists.

Computed tomography and magnetic resonance imaging of the chest are other modalities used to examine the pericardium.[7] They may help to differentiate a bacterial pericarditis from other conditions involving the pericardium. Occult or unsuspected pericarditis has been discerned with radionuclide techniques in immunocompromised patients and in trauma patients.[41,86]

A pericardial effusion may be diagnosed by noticing a discrepancy between the position of a catheter placed adjacent to the lateral wall of the right atrium and the right cardiac border. An injection of radiopaque contrast material into the right atrium may delineate these findings further. Pressure measurements at the time of cardiac catheterization reveal the elevated right atrial pressure and emphasize further the exaggeration of venous, systemic, and left ventricular pressures imposed by inspiration (see Fig. 27-2). Injection of carbon dioxide or air into the pericardium percutaneously may delineate further the pericardial effusion fluoroscopically and differentiate freely moving fluid from loculated areas (Fig. 27-5).

The diagnosis of purulent pericarditis is established definitively only by direct examination of pericardial fluid. Purulent fluid is characterized by a predominance of polymorphonuclear leukocytes; however, it also may occur early in the course of viral and tuberculous pericarditis. Proper handling of pericardial fluid is crucial to recovery and identification of the etiologic agent, as follows:

1. Fluid should be placed directly into broth capable of supporting aerobic and anaerobic microorganisms. The fluid should be plated directly onto agar media, such as blood agar, chocolate agar, or MacConkey agar.
2. Cultures also should be submitted for identification of *M. tuberculosis*, fungi, and viruses.
3. Several slides should be prepared for immediate examination by Gram stain and stain for acid-fast bacilli. Unstained slides should be stored in case of controversy or the need for special histochemical stains.
4. Antigen detection for *S. pneumoniae* or polymerase chain reaction for other microorganisms may be useful in selected cases, particularly when the patient has received prior antimicrobial therapy.[11,65]

The causative microorganism is isolated from blood cultures in many patients. When indicated, cerebrospinal fluid also should be cultured. Because purulent pericarditis often occurs after infections of the lung or pleural space, thoracentesis can reveal the etiologic agent in many cases. Documentation of empyema together with evidence of pericardial disease correlates highly with purulent pericarditis.

Acid-fast bacilli are seen on stained smears of pericardial fluid from 15 to 42 percent of patients with tuberculous pericarditis.[5] Examination of pericardial biopsy specimens by routine methods and with special stains such as the auramine O can increase the frequency of identification of *M. tuberculosis*.[75] A negative purified protein derivative skin test does not exclude the diagnosis of tuberculous pericarditis.

Grossly bloody pericardial fluid is observed frequently in patients with *Histoplasma* pericarditis, and an aspirate of the effusion reveals a predominance of mononuclear leukocytes. Growth of *H. capsulatum* from pericardial fluid rarely is successful. Showing the typical intracellular yeast forms on special stain of pericardial tissue also is helpful. Elevation of the yeast phase of the

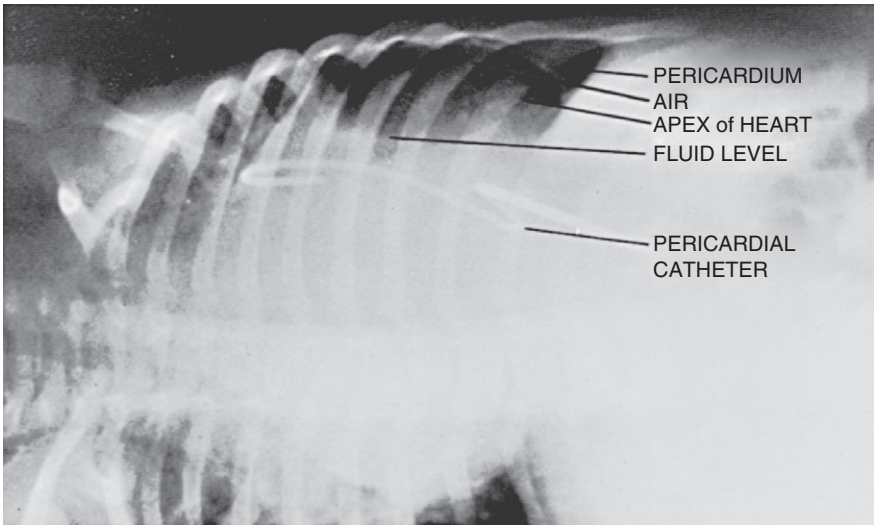

FIGURE 27-5 ■ Chest radiograph of a patient lying on the right side with a catheter in the pericardium. Air has been injected through the catheter, outlining the pericardium and fluid within the sac.

complement-fixation titer in pericardial fluid allows one to make a more rapid diagnosis.[80] Serum precipitin antibodies to *H. capsulatum* also indicate acute histoplasmosis and are helpful when present. Detecting the polysaccharide of *H. capsulatum* in urine or other body fluids is a rapid and sensitive means by which to establish the diagnosis of histoplasmosis.

Differential Diagnosis

Any patient with a rapidly increasing heart size in the absence of increasing pulmonary vascular markings should be suspected to have a pericardial effusion. Purulent pericarditis must be differentiated from pericardial effusion caused by collagen diseases, other infectious agents (e.g., viral, tuberculous, rickettsial, protozoan), neoplastic disorders, metabolic disorders, and congestive heart failure.[15] Glycogen storage disease, congenital heart disease, primary myocardial disease, cardiac tumors, and coronary artery aberrations (i.e., anomalous origin from the pulmonary artery, medial wall necrosis, and Kawasaki disease) may be confused with pericardial effusion.[15] Appropriate analysis of pericardial fluid usually permits differentiation of purulent pericarditis from pericarditis caused by other disorders. A high eosinophil count in the pericardial fluid suggests a parasite or a hypereosinophilic syndrome.[89]

Treatment

Purulent pericarditis is a potentially life-threatening illness that requires pericardial decompression and open drainage, appropriate antimicrobial therapy, and intense supportive therapy. Ainger[1] stated that more than half of children with purulent pericarditis require early or emergency drainage of the pericardium for relief of critical tamponade. Although bedside needle pericardiocentesis may be lifesaving or necessary for establishing a rapid diagnosis, Fowler and Manitsas[32] reported three deaths related to pericardiocentesis performed by inexperienced physicians. Complications include arrhythmias resulting from myocardial injury, laceration of the coronary arteries leading to hemopericardium and tamponade, and pneumothorax. Ledbetter[64] described a 10-year-old girl with staphylococcal pericarditis who developed an aortic aneurysm after undergoing multiple pericardiocentesis procedures for recurrent tamponade. The subxiphoid approach is recommended.[48]

Decompression and drainage of the pericardium are safest in a controlled environment, such as in an operating room or under fluoroscopy in the catheterization laboratory. If the patient is awake and agitated, premedication may be required.

If pericardiocentesis does not relieve symptoms successfully, and evidence of tamponade continues, immediate surgical drainage is necessary. Multiple attempts may prove unsuccessful and can lead to serious complications. The pus surrounding the heart may be too thick to be aspirated, as has been seen especially with *H. influenzae* infection.[71] Surgical creation of a pericardial window with a drain occasionally is necessary for complete removal of fluid, which accumulates rapidly. In preparation for evacuation of the pericardial fluid during tamponade, adequate cardiac output can be maintained by stimulating the heart with pharmacologic agents that cause a chronotropic and an inotropic effect.

Data from references 4, 33, 59, and 74.

Medications that tend to decrease heart rate and intravascular volume are contraindicated because they compromise the patient further.[99] Wyler and colleagues warn against the use of halothane anesthesia because of its known depressant effect on myocardial function.[99]

Controversy exists regarding the approach and extent of surgery.* A left anterolateral thoracotomy through the fifth intercostal space or a subxiphoid approach with removal of the xiphoid process seems best. Some surgeons favor the creation of a pericardial "window"; however, others favor more extensive removal of pericardial tissue. This decision may be influenced by the severity of pericardial inflammation or the presence of bloody pericardial fluid because these conditions have greater potential for producing acute or chronic constriction. Care must be taken during the procedure not to injure the phrenic nerves.

Morgan and colleagues[71] reviewed 15 children with purulent pericarditis between 1971 and 1981. *H. influenzae* occurred in 7 of these children. Most patients had pericardiocentesis followed by an anterior interphrenic pericardiectomy and recovered completely. In a series of 9 children with *H. influenzae* pericarditis, all received a limited left thoracotomy with subxiphoid approach for pericardiostomy, and no deaths occurred.[17] Video-assisted thoracoscopic approaches to managing pericarditis have been described, but further experience is necessary for pediatric patients.[68] For selected patients for whom surgery cannot be performed in a timely manner, the instillation of intrapericardial streptokinase or urokinase or other thrombolytic agents has been successful in draining purulent pericarditis and preventing the need for a more extensive surgical procedure.[56]

Antimicrobial therapy alone is insufficient for the successful treatment of purulent pericarditis. The survival of patients with purulent pericarditis is improved significantly when early pericardial drainage is performed (Table 27-3). In the preantibiotic era, draining the pericardium decreased the mortality rate from nearly 100 percent to 45 percent.[6] Occasionally, patients with meningococcal pericarditis have been managed successfully without pericardial drainage.[20] Fyfe and colleagues[35] described 73 of 79 patients with *H. influenzae* pericarditis seen between 1928 and 1984. The mortality rate before 1960 was 64 percent (7 of 11 patients), although five of

*References 29, 32, 33, 62, 72, 85.

seven deaths were reported before the antibiotic era. From 1960 to 1969, the mortality rate was 36 percent, and from 1970 to 1979, it decreased to 11.5 percent. From 1980 to 1984, 25 cases with no mortality were reported.

When the etiologic agent cannot be detected rapidly, the initial antibiotic regimen should consist of two or more drugs. Because *S. aureus* is a major pathogen and community-associated methicillin-resistant *S. aureus* isolates are common in almost all areas, a penicillinase-resistant penicillin, such as nafcillin or oxacillin, in a dose of 200 mg/kg/24 hr (maximum 12 g) plus vancomycin in a dose of 60 mg/kg/day in four divided doses is usually recommended for initial empirical therapy. Vancomycin is also recommended when strains of *S. pneumoniae* resistant to the extended-spectrum cephalosporins are present or when the infection is nosocomially acquired. Cefotaxime 200 to 300 mg/kg/day in three or four divided doses or ceftriaxone 100 mg/kg/day in one or two doses should be administered to provide protection against *S. pneumoniae* (including penicillin-resistant strains), *N. meningitidis*, and *H. influenzae* type b (for children who may be inadequately immunized).

An aminoglycoside antibiotic should be added to the just-mentioned combined drug therapy when purulent pericarditis occurs after cardiac surgery, in association with genitourinary infections, or in the immunocompromised host. The antibiotics selected for empirical therapy for acute pericarditis complicating recent cardiac surgery are influenced by the hospital's antibiogram. For patients who are allergic to penicillin, vancomycin, clindamycin, or cefazolin is substituted for the treatment of susceptible *S. aureus*.

The duration of therapy is empirical and is determined partly by the nature of concomitant infection. Generally, after a pathogen is isolated and the antimicrobial susceptibilities are known, the most specific antimicrobial agent is continued intravenously for 3 to 4 weeks. Monitoring the C-reactive protein levels may help in determining the length of treatment.[53]

Using antimicrobial agents to treat tuberculous pericarditis has had a major impact on mortality. Before their use, the mortality rate in the acute phase was 80 to 90 percent. The other 10 to 20 percent of patients died of constrictive pericarditis or miliary tuberculosis.[78] The use of three or four drugs, including isoniazid, pyrazinamide, rifampin, and possibly streptomycin, for 9 to 12 months is recommended. The role of corticosteroids in preventing progression to constriction or decreasing mortality is unclear.[25,69,78] In selected cases, pericardiectomy may be indicated to prevent constrictive pericarditis. The reader is referred to Chapter 203 on histoplasmosis for details regarding treatment of pericarditis due to this organism.

As with bacterial pericarditis, open pericardiectomy is crucial for the successful treatment of *Candida* pericarditis.[74,84]

General supportive therapy in the acute stage of infection may include the administration of oxygen, volume expansion to increase ventricular filling pressure, and cardiovascular agents to facilitate systolic emptying. The input of pediatric cardiologists is critical for the optimal management of these patients. Serial electrocardiograms may indicate the presence of occult arrhythmias and alert the physician to the degree of myocardial involvement. The patient must be monitored carefully for signs of reaccumulation of pericardial fluid and for the development of acute constrictive pericarditis. Strauss and colleagues[93] reported this complication in 2 of 12 children with purulent pericarditis. Acute constriction may develop within weeks of the initial pericardial infection[4,9] and has been reported at 8 days.[83] Constrictive pericarditis may be suspected by increasing jugular and central venous pressure, weight gain, enlarging liver, worsening dyspnea, and decreased urinary output. The persistence of heart failure when the cardiac silhouette is becoming smaller also suggests the development of constrictive pericarditis. Complete pericardiectomy should be performed promptly when constriction is suspected.

Prognosis

Accurate mortality rates are difficult to compute from the literature because of the relative rarity of this infection as well as the nature and severity of any underlying disease. Factors that contribute to mortality are delay in recognition, absence of early surgical drainage, presence of cardiac tamponade, degree of myocardial involvement, etiologic agent (particularly *S. aureus*), and age of the patient. Long-term follow-up of children with purulent pericarditis is recommended. They should be observed carefully for the presence of a constrictive component as a sequela to the acute infection. Most children recover fully, however, and return to normal activity.

VIRAL PERICARDITIS

In 1951, Christian[18] suggested that viral infections were responsible for cases of idiopathic or benign pericarditis. A viral cause has not been substantiated in many patients, however.

Etiology

The principal viruses implicated in pericarditis are the coxsackieviruses.[74] Adenoviruses have been recovered less frequently.[55] Associations with varicella,[96] cytomegalovirus,[13] smallpox vaccinations, influenza,[47] (including H1N1),[60] influenza vaccinations,[94] and infectious mononucleosis[51,88] have been reported.

Clinical Manifestations

In 40 to 75 percent of cases, the patient has a history of upper respiratory tract infection for 10 days to 2 weeks preceding the onset of symptoms. Fever and chest and abdominal pain are the most common symptoms.[18] A friction rub may be heard in 50 to 80 percent of cases.[98] Children with viral pericarditis generally are less toxic and experience smaller elevations in body temperature than do children with purulent pericarditis. Some appear acutely ill, however. Large amounts of pericardial fluid accumulation and tamponade are rare findings.

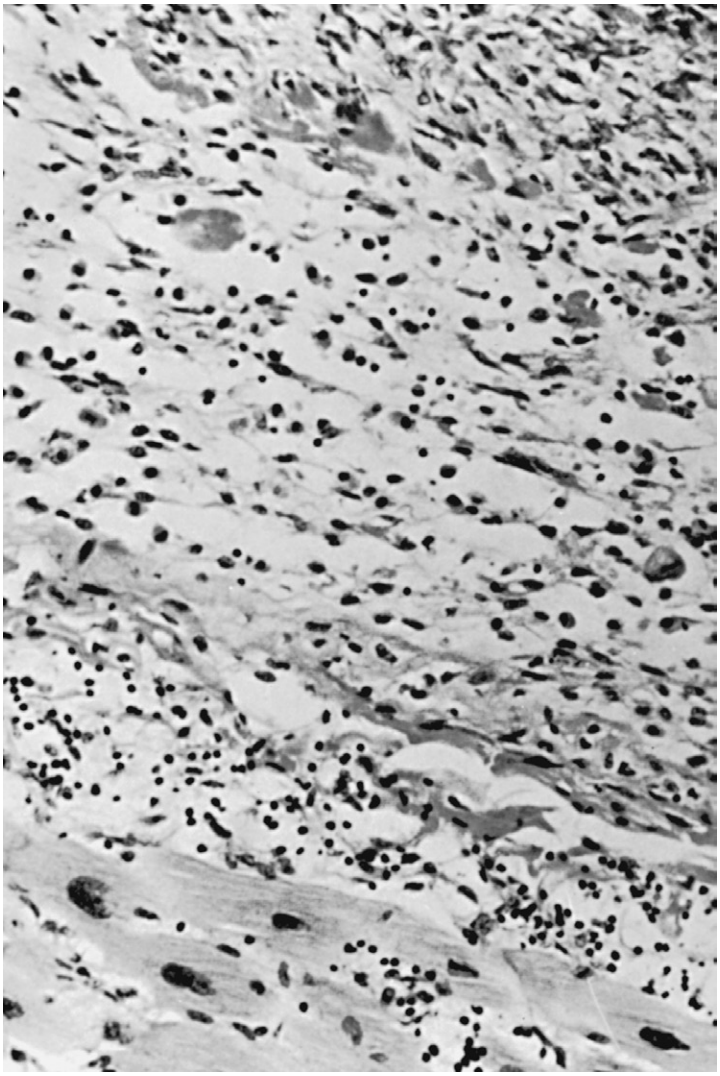

FIGURE 27-6 ■ In this case of viral pericarditis there is a layer of fibrin and fibroblasts along the pericardial surface. The mononuclear cell infiltrate in the epicardium extends into the outer myocardium (H&E, ×400). (Courtesy Edith P. Hawkins, MD, Texas Children's Hospital, Houston.)

Investigative Techniques

The electrocardiographic, radiographic, echocardiographic, and nuclear scanning findings described for patients with purulent pericarditis also are observed in patients with viral pericarditis. The peripheral leukocyte count may reveal fewer polymorphonuclear leukocytes than in patients with bacterial pericarditis. Mononuclear cell infiltrates in the pericardium with extension into the myocardium may be seen (Fig. 27-6).

If obtained, pericardial fluid should be sent for cell count and viral culture. Nasopharyngeal and rectal samples also should be obtained and cultured for viruses. Molecular methods may detect evidence of a specific virus. Acute and convalescent sera should be obtained so that appropriate titers can be measured if a virus is isolated.

Course and Prognosis

Viral pericarditis generally resolves spontaneously over the course of 3 to 4 weeks.[74] Large pericardial effusions and tamponade are rare occurrences.[15] Generally, bed rest for approximately 1 week and analgesics for pain are the only therapy that is required. Constrictive pericarditis is a rare occurrence, but pericarditis may recur.[74] In adults with recurrent pericarditis, colchicine appears to be of more benefit than corticosteroids in terms of treatment effect and decreased recurrences.[67]

CHAPTER 28

Myocarditis

Jesus G. Vallejo

Myocarditis is defined clinically and pathologically as inflammation of the myocardium. The clinical presentation and cause may be quite varied. This entity may go unrecognized in numerous patients whose illness may resolve spontaneously, or it may lead to significant morbidity and mortality.

In the early part of the 20th century, most cases of myocarditis were classified as idiopathic, and a diffuse or focal interstitial inflammation was identified on histologic examination. Rheumatic fever, diphtheria, and other bacterial infections were the only diseases recognized as associated with myocarditis, although some experts suspected that viruses might play a significant etiologic role in many cases.[151] After the discovery in 1947 of the coxsackievirus group and the subsequent isolation and identification of other viruses, the number of cases of myocarditis classified as idiopathic diminished rapidly.[34]

EPIDEMIOLOGY

The diverse clinical manifestations have made the true incidence of myocarditis difficult to determine. The clinical course of acute myocarditis can be insidious, with limited inflammation and cardiac dysfunction, or it can be overwhelming, leading to severe cardiac injury and cardiac failure. As a clinical entity, myocarditis is an uncommon occurrence in children. At Texas Children's Hospital, Houston, Texas, between 1954 and 1977, myocarditis represented 0.3 percent of the 14,322 patients seen by the Cardiology Service.

Because not all cases of myocarditis are recognized clinically, a much higher incidence is recorded in autopsy series. An autopsy incidence of 1.15 percent was found from 4343 studies performed between 1954 and 1977 at Texas Children's Hospital. This rate is considerably lower than the incidence of 6.83 percent reported by Saphir and Simon[150] in 1944 for 1420 autopsies performed on children. In Saphir's series, 32 of 97 cases had or probably had rheumatic carditis,[151] whereas only 2 cases occurred in the Texas Children's Hospital series. The discrepancy is even more pronounced when these observations are compared with those of Burch and colleagues,[25] who demonstrated evidence of interstitial myocarditis in the hearts of 29 of 50 infants and who showed evidence of interstitial myocarditis in the hearts of 29 of 50 infants and young children undergoing routine postmortem studies.

Some of the discrepancies between the clinical and autopsy series may be explained by the fact that the manifestations of myocarditis are subclinical in many cases and may be recognized only by changes on electrocardiogram (ECG) or perhaps not at all. In many instances, myocarditis is only one component of a generalized illness, and the cardiac dysfunction, if mild, may be overlooked.

ETIOLOGIES

Myocarditis may occur with many common infectious illnesses that affect infants and children (Table 28-1). In most cases of myocarditis, the etiologic agent is never identified, however. In the United States and Western

Hypersensitivity/ autoimmunity	Rheumatoid arthritis Rheumatic fever Ulcerative colitis Systemic lupus erythematosus
Other	Sarcoidosis Scleroderma Idiopathic Cornstarch

Europe, viruses are the most common causes of acute myocarditis. Myocarditis generally is a sporadic disease, but epidemics have been reported. Most epidemics have been caused by coxsackievirus group B and have affected infants in the newborn period.[42,47] Gear and Measroch[58] were the first to identify coxsackievirus B in association with myocarditis after an epidemic occurred in a nursery in a maternity home in southern Rhodesia.

The association between virus infection and the development of myocardial disease also was made by Grist and Bell,[66] who presented comprehensive serologic data correlating enterovirus infection with acute viral myocarditis. In the World Health Organization record during the 10-year period from 1975 through 1985, the coxsackieviruses B represented the most frequent inflammatory agents in cardiovascular disease (34.6/1000), followed by influenza B virus (17.4/1000), influenza A virus (11.7/1000), coxsackievirus A (9.1/1000), and cytomegalovirus (CMV) (8/1000).[26] Karjalainen and colleagues[85] prospectively examined 104 conscripts during the 1978 influenza A virus (H1N1) epidemic in Sweden. The incidence of myocarditis was 9 percent of the 67 verified cases of influenza virus infection. Randolph and colleagues[139] reported that of 838 children with pandemic H1N1 admitted to a pediatric intensive care unit, 1.4 percent were diagnosed with myocarditis. Although H1N1-related acute myocarditis was uncommon, it was found to be an independent risk factor for death.

The development of molecular techniques such as polymerase chain reaction (PCR) has improved the testing of endomyocardial biopsy specimens for potential viral pathogens. A study using PCR identified viral genome in 38 percent of endomyocardial biopsy specimens from patients diagnosed with acute myocarditis.[23] Of the positive PCR samples, 23 percent were positive for adenovirus, 14 percent for enterovirus, and 3 percent for CMV. Parvovirus B19, influenza A virus, Epstein-Barr virus, herpes simplex virus (HSV), and respiratory syncytial virus were detected in less than 1 percent of cases.

Investigators also have speculated for decades on the possibility that acute myocarditis is a common forerunner of idiopathic dilated cardiomyopathy. Evidence supporting this hypothesis was presented first by Orinius and Pernow,[133] who found cardiac disease in humans years after an apparent uncomplicated coxsackievirus infection. Subsequently, Bowles and colleagues[22] using a slot-blot hybridization technique provided conclusive evidence for the presence of enterovirus in endomyocardial biopsy samples from patients with dilated cardiomyopathy. In another study, Bowles and associates[23] detected viral genomes in 20 percent of 149 patients with the diagnosis of dilated cardiomyopathy. In these patients, adenovirus was identified in 12 percent and enterovirus in 8 percent of cases. In all age groups, adenovirus and enterovirus were the viruses most commonly detected in acute myocarditis and dilated cardiomyopathy.

In December 2002, the U.S. Department of Defense began mandatory smallpox vaccination for select service members and employees without contraindications to vaccination, and in January 2003, the U.S. Department of Health and Human Services implemented a voluntary civilian smallpox vaccination program. As of June 15, 2003, the Department of Defense identified more than 50 cases of suspected, probable, or confirmed myopericarditis occurring within 30 days of vaccination in these individuals, based on clinical evaluation of symptoms, ECG, cardiac enzyme assays, echocardiography, and the exclusion of ischemic coronary artery disease. Myocarditis occurred in 7.8/100,000 primary vaccinees in the U.S. army, an incidence that was 3.6-fold more than that in unvaccinated individuals.[68]

PATHOLOGY

Isolated or idiopathic myocarditis is a rare pathologic entity. The pathologic cardiac findings usually are nonspecific; similar gross and microscopic changes occur regardless of the causative agent.[62,129,137,145] Grossly, all four chambers of the heart are enlarged, and the cardiac weight is increased. The heart usually is flabby and pale. In some instances, especially with coxsackievirus B infections, petechial hemorrhages may be seen on the epicardial surfaces; pericardial fluid may be tinged with blood. On cut section, the ventricular muscle walls may be thinned. Occasionally, the ventricles are hypertrophied or increased in thickness because of edema. The valves are spared. The endocardial surface usually is unaffected but occasionally may be thickened and appear glistening white. This important observation suggested to some investigators that endocardial fibroelastosis, which manifests as congestive cardiomyopathy, represented a progression from acute viral myocarditis.[71,80] In a study of 64 hearts of children who had myocarditis or endocardial fibroelastosis, Hutchins and Vie[80] found 18 with endocardial fibroelastosis only, 5 with myocarditis only, and 41 with features of both diseases. When time from onset of illness to death was 2 weeks or less, only myocarditis was evident. When the time interval was 2 weeks to 4 months, a combined picture was seen, whereas only endocardial fibroelastosis with trivial myocarditis was evident when the time from onset of disease to death was more than 4 months.

These findings were supported further by Hastreiter and Miller,[71] who found microscopic evidence of myocarditis after transthoracic needle biopsy of the myocardium in a child who had the classic clinical picture of endocardial fibroelastosis, including left ventricular hypertrophy on ECG. Fruhling and associates[53] extended these observations by showing coxsackievirus B3 in the myocardium of 13 of 28 infants with endocardial fibroelastosis. Ni and associates[128] analyzed 29 myocardial samples from patients with autopsy-proven endocardial fibroelastosis using specific PCR for enterovirus, adenovirus, mumps, CMV, parvovirus, influenza, and HSV. In 90 percent of samples, viral genome was amplified; more than 70 percent of the samples were positive for mumps viral RNA, and 28 percent amplified adenovirus. These data suggest that endocardial fibroelastosis also is a sequela of mumps virus infection.

The microscopic picture of acute myocarditis typically shows a focal or diffuse interstitial collection composed predominantly of mononuclear cells, lymphocytes, plasma cells, and eosinophils. Polymorphonuclear leukocytes rarely are seen, unless the cause of the carditis is bacterial. Virus particles and inclusion bodies rarely are recognized.[140,145] In severe infections caused by any agent, but especially coxsackieviruses and diphtheria, a loss of cross-striation in the muscle fibers, edema, and, sometimes, extensive necrosis of the myocardium occur. The diphtheria exotoxin has a particular affinity for conductive tissue; dysrhythmias, including complete heart block, are common findings in this form of myocarditis. The exotoxin interferes with protein synthesis by inhibiting a translocating enzyme in the delivery of amino acids.

Myocarditis seen with bacterial infections usually differs from that of presumed viral origin (Figs. 28-1 to 28-4). Microabscesses and patchy focal suppurative changes may be observed. Frequently, perimyocarditis may be seen with concomitant bacterial infection of the pericardium and myocardium.

Giant cells with or without granulomata are markers for the diagnosis of giant cell myocarditis.[79] Granulomata have been observed in the myocardium of patients with tuberculosis, syphilis, rheumatoid arthritis, rheumatic heart disease, sarcoidosis, and certain fungal and parasitic infections. Occasionally, giant cells have been seen in interstitial myocarditis (idiopathic or Fiedler). In many cases, giant cell myocarditis occurs, but no cause is found.

Two types of giant cells are recognized, one of which seems to be myogenic in origin and is thought to represent transitional forms of myocardial fibers. This type of cell has been found without granulomata. The second,

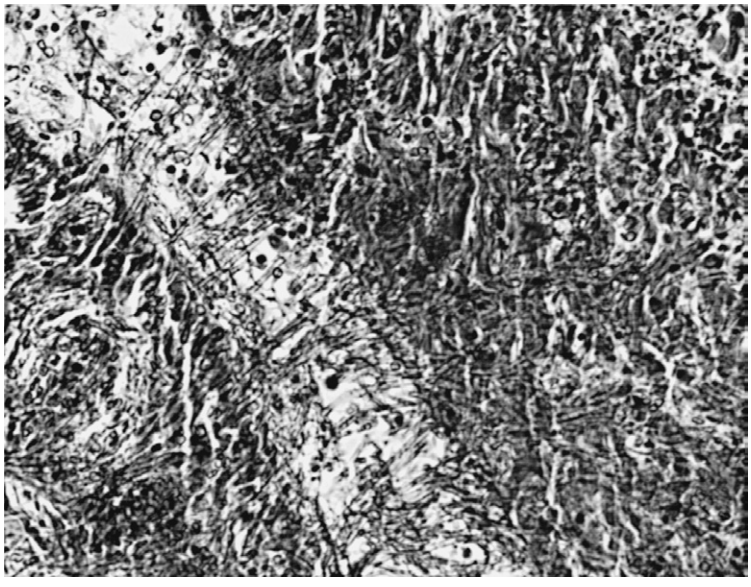

FIGURE 28-1 ■ *Candida albicans* myocarditis. Note the focal necrosis of the myocardium with central masses of hyphae and necrotic debris surrounded by mononuclear cell infiltrate. (Hematoxylin-eosin stain; ×160.) (Courtesy Edith Hawkins, MD. Houston, Tex.)

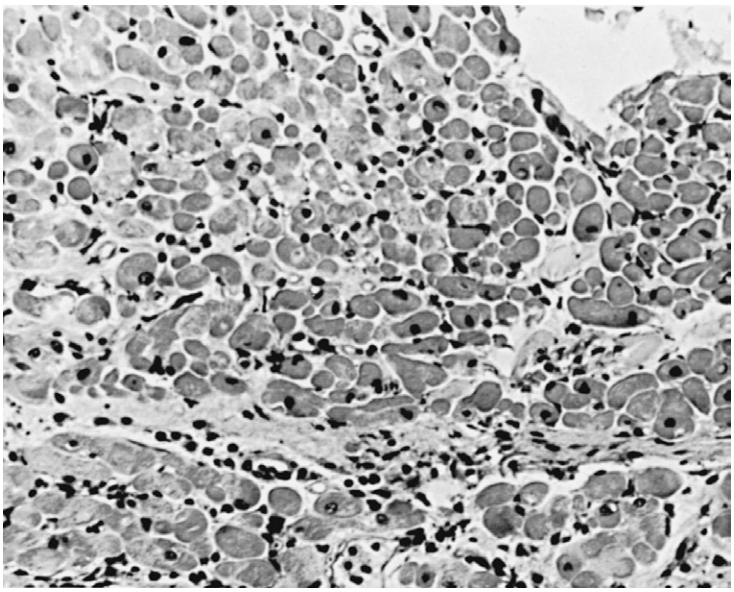

FIGURE 28-2 ■ Right ventricular biopsy specimen. The presumed viral myocarditis is characterized by focal mononuclear cell infiltrates. (Hematoxylin-eosin stain; ×160.) (Courtesy Edith Hawkins, MD. Houston, Tex.)

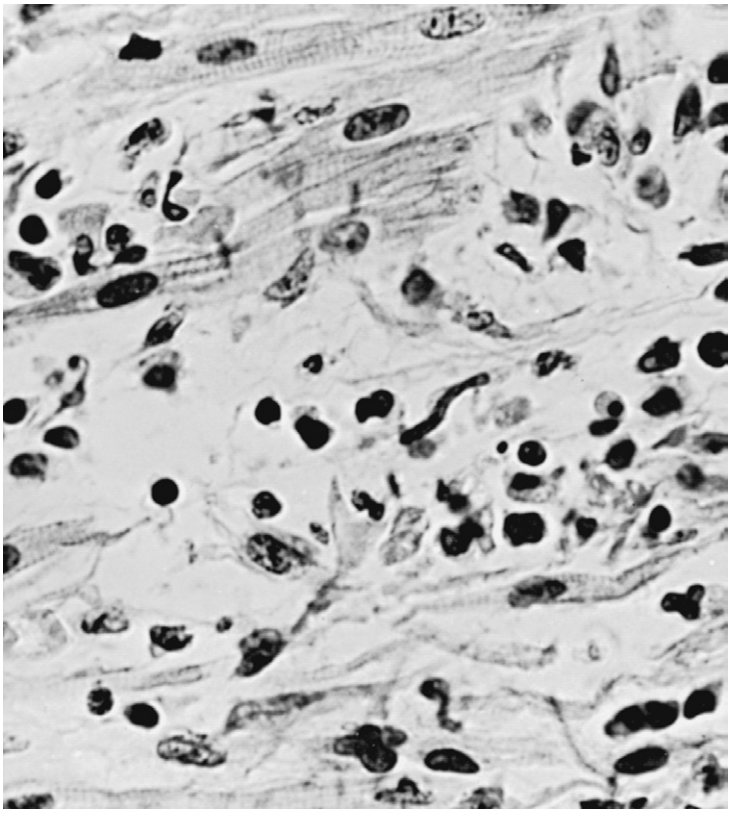

FIGURE 28-3 ■ Picornavirus myocarditis characterized by interstitial edema, mononuclear cell infiltrates, and focal myofiber disruption. (Hematoxylin-eosin stain; ×400). (Courtesy Edith Hawkins, MD. Houston, Tex.)

more characteristic giant cell probably is derived from interstitial histiocytes. The latter type typically is seen in patients with myocarditis of nonviral cause, whereas the former is a response to viral infection.

PATHOGENESIS

The pathogenesis of myocarditis is poorly understood, insofar as the disease progresses through different phases with distinctly different mechanisms and clinical manifestations. The pathophysiology of myocarditis in humans was derived largely from experimental models of coxsackievirus infection. More recently, Liu and Mason[104] suggested that myocarditis should be viewed as a continuum that comprises three separate phases: acute viral infection (phase I), autoimmunity (phase II), and dilated cardiomyopathy (phase III).

Phase I of the disease is triggered by entry and proliferation in the myocardium of the causative virus. Impairment of left ventricular function in mice with histopathologically graded moderate cellular infiltration

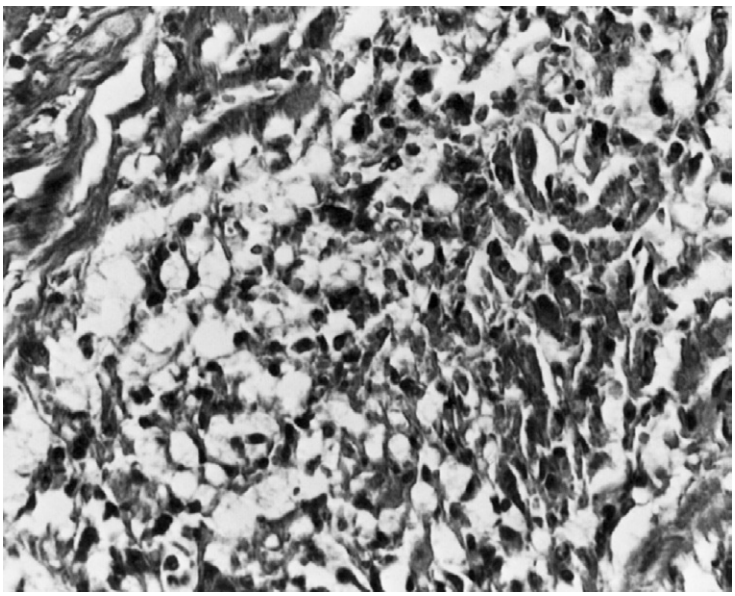

FIGURE 28-4 ■ Section of myocardium. Vaccinia (smallpox vaccine) myocarditis. Note mononuclear cell infiltrates and fatty degenerative changes. (Hematoxylin-eosin stain; ×400). (Courtesy Edith Hawkins, MD. Houston, Tex.)

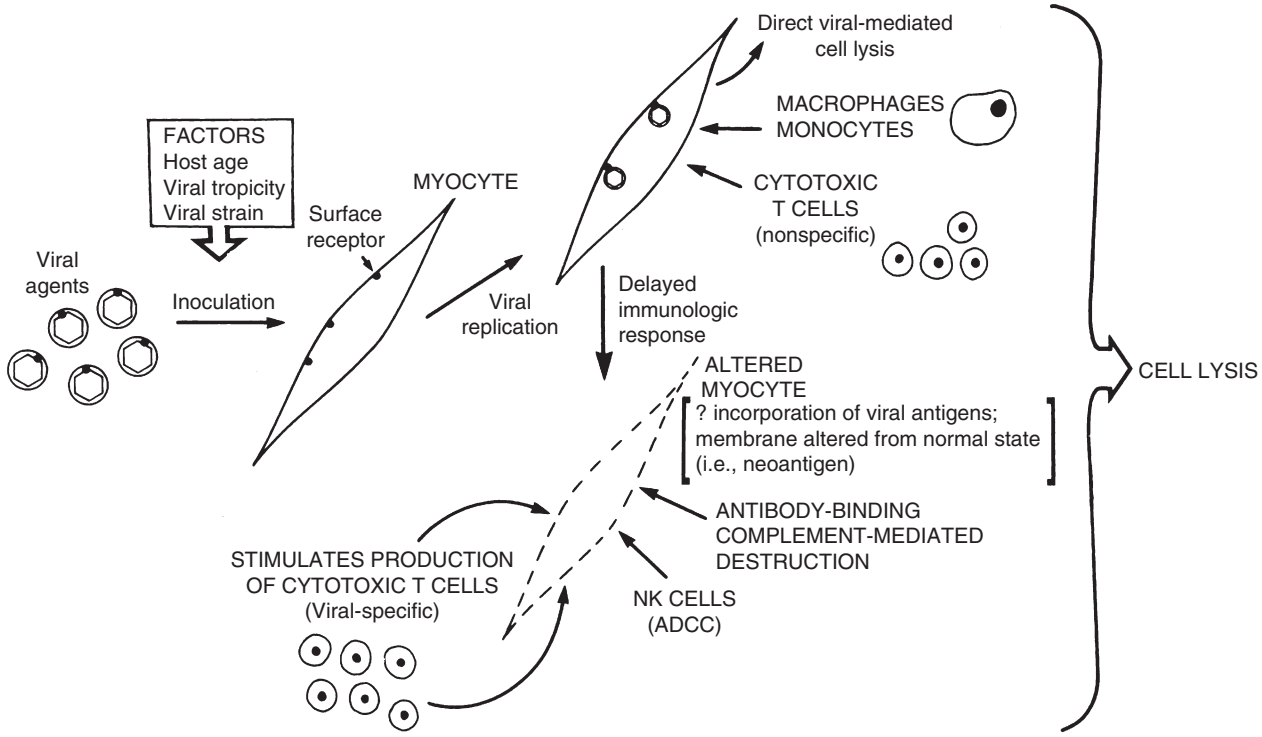

FIGURE 28-5 ■ Schema for pathogenesis of myocarditis. Viral agents attach to cells by means of surface receptors. After a cell is infected, the cell cycle is changed. Direct virus-mediated cytolysis occurs. Cellular effectors of injury (i.e., macrophages, monocytes, and nonspecific cytotoxic T cells) are involved in the primary reaction. Myocytes that survive are altered in their structure. Cytotoxic T cells specifically targeted against the altered myocyte, natural killer (NK) cells, and complement-activated, antibody-mediated cardiocytolysis or antibody-dependent cellular cytotoxicity (ADCC) participate in the secondary reaction. (Modified from Maisch B, Trostel-Soeder R, Stechemesser E, et al. Diagnostic relevance of humoral and cell-mediated immune reactions in patients with acute viral myocarditis. *Clin Exp Immunol* 1982;**48**:533.)

after coxsackievirus B3 infection supports the important pathophysiologic role of direct viral damage of the myocardium.[167] Phase I concludes with activation of the cellular immune response, which attenuates viral proliferation but also may enhance cardiac injury. Ideally, the immune response should downregulate to a resting state when viral proliferation is controlled. If immune activation continues unabated despite elimination of the virus, autoimmune disease may result, initiating phase II of the disease. The continuous activation of T cells long after viral clearance occurs is detrimental to the host because cytokine-mediated and direct T-cell–mediated myocyte injury leads to impairment of contractile function (Fig. 28-5). Long-term remodeling and progression

to dilated cardiomyopathy characterize phase III of the disease.[76]

The basic function of innate immunity is restriction of the early proliferation of infectious agents. Numerous effector cells and molecules work in concert to restrict this initial spread of an infectious focus. The responding cells include natural killer cells, natural killer/T cells, and γδ T cells. Several lines of evidence suggest that mediators of the innate immune system, such as tumor necrosis factor (TNF) and nitric oxide, play an important role in the pathogenesis of viral myocarditis.[114,189] Elevated levels of TNF have been reported in patients with viral myocarditis, and TNF mRNA and protein are consistently upregulated in the hearts of these patients.[116,152] In mice, the exogenous administration of TNF aggravates myocarditis and the neutralization of TNF by antibodies or soluble receptors attenuates the disease.[94,186] These data suggest that TNF production is detrimental in the setting of myocarditis.

More recent studies also have shown that TNF and nitric oxide are beneficial to the host by virtue of their antiviral effects. Mice with defective TNF or nitric oxide expression have increased myocardial injury, a significant increase in viral titers in the heart, and significantly higher mortality rates after infection with encephalomyocarditis virus (EMCV) or coxsackievirus B3.[175,189] These observations highlight the complexity of the innate immune response and suggest that innate immune mechanisms play a dual role in the setting of viral myocarditis. Although the prevailing notion has been that production of cytokine in the heart during viral infection is detrimental, the host–pathogen relationship is changed fundamentally when the host is unable to produce molecules such as TNF or nitric oxide.[175,189]

An important component of the innate immune system uses pattern recognition receptors, such as the Toll-like receptors (TLRs), to recognize pathogen-associated molecular patterns present in microbes.[4] TLRs induce the production of cytokines and interferons (IFNs) and modulate the adaptive immune response. Understanding of the role of TLRs in the pathogenesis of viral myocarditis is still evolving. However, recent studies suggest that cardiac inflammation during viral infection depends on TLRs. The viral genome replicates using the positive-strand RNA as its template, resulting in the formation of double-strand RNA (dsRNA) intermediates. Accordingly, both single-strand RNA (ssRNA) and dsRNA are present in virally infected cells. TLR3 and TLR7/8 signaling are activated by dsRNA and ssRNA, respectively, whereas TLR9 recognizes bacterial and viral CpG DNA motifs. Thus, viral infection can activate innate immune signaling in the heart through myeloid differentiation factor (MyD)88 dependent (TLR7/8/9) and MyD88 independent pathways (TLR3). Fairweather and colleagues[48] reported that mice with defective TLR4 signaling had decreased coxsackievirus B3 replication and less severe myocarditis 12 days after infection compared with wild-type mice. The presence of TLR4 also was associated with increased production of interleukin (IL)-1β and IL-18 and increased viral replication in the heart.

In a similar study, Fuse and associates[55] reported that mice deficient in MyD88, an adapter protein involved in TLR signaling (except TLR3), also had less myocarditis and attenuated viral replication in the heart after infection with coxsackievirus B3. Coxsackievirus B3-infected, MyD88-deficient mice had significantly higher levels of IFN-β but reduced expression of the coxsackievirus-adenovirus receptor in the heart. The enhanced IFN expression and lower expression of the coxsackie-adenovirus receptor in the heart could explain the attenuation of disease in the MyD88-deficient mice. Infection of TLR3-deficient mice with EMCV, a positive ssRNA virus, resulted in earlier mortality in TLR3-deficient mice that was associated with increased viral replication and myocardial injury in contrast to wild-type mice.[69] Similar observations have been reported for coxsackievirus group B serotype 3 in TLR3-deficient mice.[127] The final answer on the role of TLRs in the pathogenesis of viral myocarditis awaits further investigation, however.

Although the host genetic factors responsible for the changes observed in the three phases of myocarditis have yet to be defined completely, Woodruff and Woodruff,[183] using a murine model, were the first to show a role for T lymphocytes in the pathogenesis of viral myocarditis. In this study, depletion of T lymphocytes using antithymocyte serum or thymectomy and irradiation led to a decrease in mortality rates and in the inflammatory infiltrate after CVB3 infection. Huber and associates,[78] using BALB/c mice infected with coxsackievirus B3, showed that cytolytic T cells were the agents responsible for the major part of myocardial cell injury. In addition, proinflammatory mediators, such as TNF, released by infiltration cells also adversely affect cardiac function.

Opavsky and colleagues[132] defined the specific contributions of T-cell subsets (CD4 and CD8) and the T-cell receptor β chain to the pathogenesis of viral myocarditis. When $CD4^{-/-}$ or $CD8^{-/-}$ mice were exposed to CVB3, loss of $CD8^{+/+}$ immune cells did not affect survival significantly, but viral proliferation was attenuated. In contrast, $CD4^{-/-}$ mice showed a trend toward an improvement in survival and a small but significant decrease in the inflammatory infiltrate at 14 days after infection. Mice deficient in CD4/CD8 immune cells and T-cell receptor β had the best outcome in terms of decreased mortality. A marked decrease in inflammatory infiltrate was noted in CD4/CD8 double knockout mice. Although no significant change occurred in viral titers, a marked decrease in myocardial TNF mRNA 4 days after infection was seen in CD4/CD8 double knockout mice. These same investigators have shown that the T-cell receptor–associated tyrosine kinase $p56^{lck}$ is crucial for coxsackievirus B3 proliferation in the heart and activation of T cells to target the heart.[103] Mice deficient in $p56^{lck}$ were protected against the development of myocarditis, providing further support for the hypothesis that T-cell activation during viral myocarditis contributes to increased inflammation and myocyte destruction in the host.

T-regulatory (T-reg) cells are important in modulating the inflammatory response and preventing development of autoimmunity through production of cytokines such as IL-10 and tumor growth factor (TGF)-β.[181] T-regs express CD4, but they also express the α-subunit of the IL-2 receptor, CD25. They are high expressors of

the transcription factor FoxP3. Li and associates[100] have shown that the allograft of M2 (anti-inflammatory) macrophages led to improvement of virus-induced myocarditis, which was associated with enhanced levels of T-regs. Similarly, Huber and colleagues[77] reported decreased viral titers and inflammation after adoptive transfer of a $CD4^+$ $CD25^+$ regulatory-like T-cell population into a mouse model of coxsackievirus B3 infection. Thus, modulating the immune response may be critical for the prevention of chronic virus replication.

The ongoing injury that persists may be considered an autoimmune process.[78,182] At least in murine models, it is clear that both cellular and humoral autoimmunity are involved in the progression to chronic heart disease. The recently identified T helper 17 (Th17) subset has been implicated in the onset of chronic myocarditis.[70] These cells secrete high levels of IL-17 and have been implicated in the production of autoantibodies.[70,187] In a mouse model of coxsackievirus B3 myocarditis, the Th17 subset contributes to chronic myocarditis through persistent inflammatory signaling involving the secretion of IL-17. Consistent with this, considerable Th17 expansion occurs approximately 2 weeks after coxsackievirus B3 infection in mice.[188] IL-17 and its various isotypes can induce expression of TNF and Th2 responses, which leads to a prolonged inflammatory milieu that might foster the production of autoantibodies.

Autoantibodies that have been associated with myocarditis in patients and mice include those directed at cardiac myosin, adrenoreceptor adenine nucleotide translocator, and sarcolemmal and myolemmal proteins. The role played by these autoantibodies in the pathogenesis of myocarditis is unclear; antisarcolemmal antibodies that cross-react with enteroviral epitopes have been shown to damage cardiac myocytes.

More recent studies also have shed light on the mechanisms by which coxsackievirus B3 may contribute directly to the development of myocarditis and dilated cardiomyopathy. Badorff and colleagues[9-11] reported that the 2A protease encoded by coxsackievirus B3 cleaves dystrophin in cultured myocytes and in infected mouse hearts, leading to disruption of dystrophin and the dystrophin-associated glycoprotein α-sarcoglycan and β-sarcoglycan complex. Dystrophin provides a structural link between the muscle cytoskeleton and extracellular matrix to maintain muscle integrity. Xiong and associates[185] compared the effects of coxsackievirus B3 infection in dystrophin-deficient *(mdx)* and wild-type mice. Coxsackievirus B3 infection significantly enhanced sarcolemmal disruption in the *mdx* mice in contrast to wild-type mice; the disruption was detectable 2 days after infection and continued to increase after initial infection. Viral titers were higher in the hearts of *mdx* mice than in the hearts of wild-type mice, indicating greater viral replication in the absence of dystrophin. The observed differences seemed to be a result of more efficient release of coxsackievirus B3 from dystrophin-deficient myocytes. The expression of wild-type dystrophin in cultured cells decreased the cytopathic effect induced by coxsackievirus B3 and the release of virus from the cell. The expression of a cleavage-resistant mutant of the dystrophin protein inhibited coxsackievirus B3–mediated cytopathic effect and viral release further.

PATHOPHYSIOLOGY OF VENTRICULAR DYSFUNCTION IN MYOCARDITIS

With extensive interstitial inflammation, muscle cell injury, or both, myocardial contractility is reduced. Consequently, the heart enlarges and the end-diastolic volume of the ventricle increases. In the normal heart, an increase in filling volume leads, by the Starling mechanism, to an increased force of contraction, ejection fraction, and cardiac output. In patients with myocarditis, the myocardium is unable to respond in this manner and cardiac output is reduced. Systemic blood flow may be maintained, however, by use of the cardiac reserve, mediated by the sympathetic nervous system and leading to vasoconstriction of the skin vessels and an increase in heart rate. With progressive disease or any stress (e.g., infection, anemia, fever), the heart may be unable to meet the oxygen demands of the tissues, and the clinical picture of congestive cardiac failure may become evident. Increased end-diastolic volume leads to progressive increase in ventricular end-diastolic pressure, which leads to increased filling pressure, and left atrial and pulmonary venous hydrostatic pressure may be elevated above the colloid osmotic pressure, which normally prevents transudation of fluid across the capillary membranes. Pulmonary congestion and edema and systemic venous engorgement (manifested in infants primarily as hepatic enlargement) are common findings in the more acute forms of myocarditis. In some infants and young children, the presentation is predominantly that of right-sided heart failure.[144]

An appreciation of the disturbance of myocardial function may be gained from the angiographic frames shown in Figure 28-6. The left ventricle is dilated considerably, and the outline is irregular in diastole and systole. The ejection fraction is reduced significantly at 35 percent instead of the normal 60 to 75 percent.

Another means of evaluating left ventricular function is the noninvasive technique of cardiac ultrasound. Gutgesell and colleagues[67] established normal standards for children. An example is shown in Figure 28-7A.

The normal shortening fraction (i.e., percentage change in ventricular dimensions between end-diastole and end-systole) is 35 ± 4 percent, regardless of age (range 28% to 44%). Figure 28-7B illustrates the case of a 4-year-old child with idiopathic myocarditis and shows ventricular dilation with markedly reduced motion of the left ventricular posterior wall and septum, leading to a shortening fraction of only 12 percent. Further assessment of ventricular function can be achieved by measuring systolic time intervals obtained from simultaneous recording of the ECG and the semilunar valve opening and closing points on the echocardiogram.[67]

The clinical presentation of myocarditis varies with the age of the patient and the virulence of the organism. At one end of the spectrum is a fulminant, rapidly fatal illness, and at the other, no apparent clinical disturbance at all. A newborn especially is susceptible to the severe form of myocarditis usually caused by the coxsackieviruses B,[36,87] but it also is recognized with rubella[3] and HSV[184] infections and with toxoplasmosis.[79]

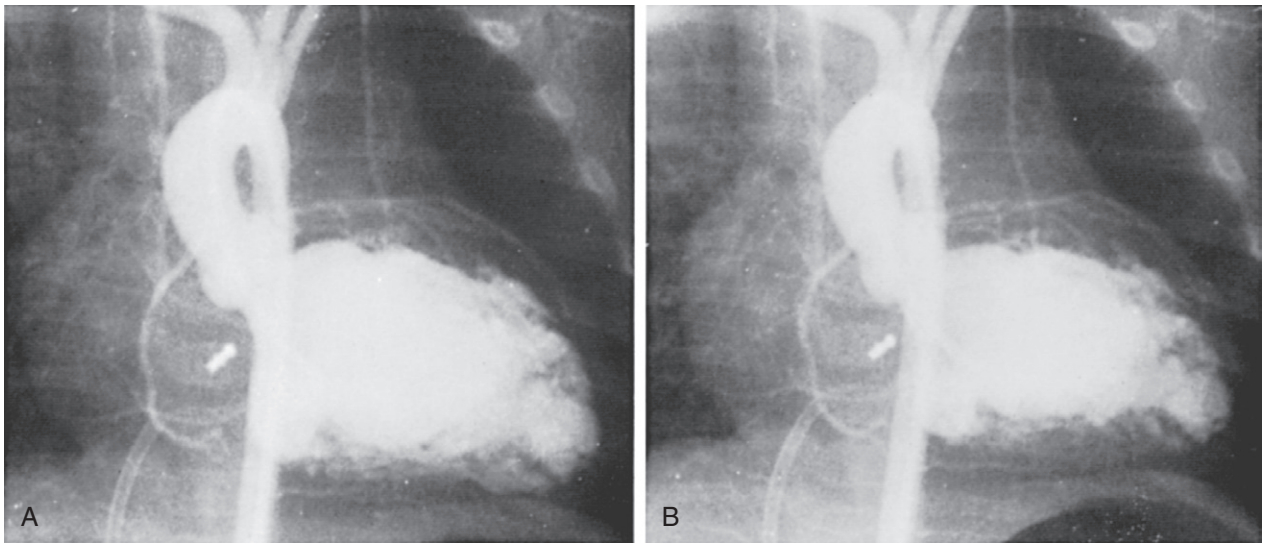

FIGURE 28-6 ■ The end-diastolic **(A)** and end-systolic **(B)** frames from a left ventriculogram of a patient with idiopathic myocarditis show irregularity of the wall and poor contractility.

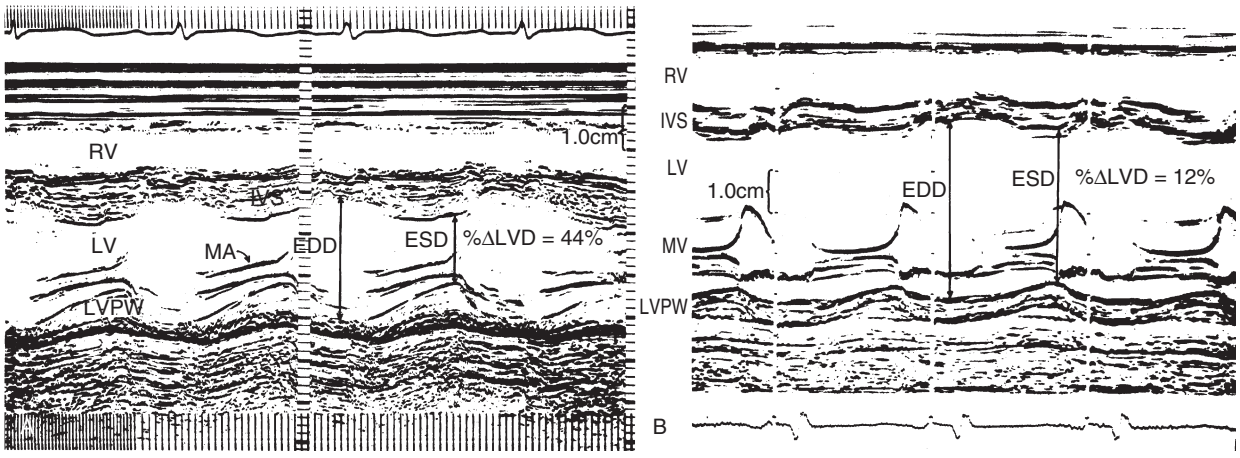

FIGURE 28-7 ■ **A,** Normal echocardiogram of a 4-year-old child. **B,** Echocardiogram of a 4-year-old child with idiopathic myocarditis shows left ventricular dilation and severely reduced shortening fraction. *EDD,* End-diastolic dimension; *ESD,* end-systolic dimension; *IVS,* interventricular septum; *LV,* left ventricle; *LVPW,* left ventricular posterior wall; *MA,* mitral apparatus; *MV,* mitral valve, %ΔLVD, percent change in left ventricular dimension (shortening fraction); *RV,* right ventricle.

In many of these infections, myocarditis is only one component of a generalized illness, often with severe hepatitis and encephalitis.[17,87] In some instances, however, infections with these organisms may produce only a mild clinical disturbance.[24,81] In the report by Brightman and colleagues,[24] a nursery epidemic of coxsackievirus B5 infection in preterm infants was recognized only by chance because a virologic survey was in progress at the time in the institution. No cases of myocarditis were documented, and all of the infants recovered. Findings included lethargy, failure to gain weight, and, in some infants, evidence of aseptic meningitis.

As described in the review by Kibrick and Benirschke[87] of 25 infants with coxsackievirus B myocarditis, vague symptoms such as lethargy and anorexia may herald the onset of the severe disease, emphasizing that close attention should be paid to all symptoms, especially in a newborn, no matter how nonspecific. Four infants had episodes of vomiting, and fever was documented for more than half of the cases; occasionally, the temperature was subnormal. Cyanosis, respiratory distress, and tachycardia, cardiomegaly, or ECG changes occurred in 19 of 23 infants. Tachypnea (a respiratory rate >60/min in a newborn) is an early sign of heart failure in a young infant and should alert the clinician to this diagnosis.

In older infants and children, the manifestations of myocarditis generally are less fulminant than manifestations in newborns.[144,149,176,180] An acute and fatal illness has been associated, however, with idiopathic myocarditis[102] and the myocarditis associated with enteroviruses,[87] adenoviruses,[72] mumps,[96] chickenpox,[134] diphtheria,[15] CMV,[170] and many of the other causative agents listed in Table 28-1. Some older children have been reported with acute, substernal chest pain consistent with angina and

have ECG changes of acute myocardial infarction.[75,118] The usual clinical picture is that of an acute or a subacute illness, which often begins with a mild upper respiratory tract infection and a low-grade fever.[8] Some infants have only vague, nonspecific suggestions of disease (e.g., irritability, periodic episodes of pallor) before the onset of cardiorespiratory symptoms, which begin a few days to 2 weeks after the onset of the initial symptoms. Abdominal pain may be a prominent complaint in some children.[176]

On examination, these infants and children often are anxious and apprehensive, but some appear apathetic and listless. Pallor may be striking, and mild cyanosis may be present. The skin may be cold and mottled. Respirations are rapid and labored, and grunting may be prominent. The pulse is thready, and blood pressure usually is normal or slightly reduced, unless the infant is in profound shock. The precordium is quiet, without a prominent cardiac impulse. Resting tachycardia invariably is present in children who are critically ill with myocarditis. The heart sounds are muffled, and a prominent gallop rhythm usually is heard. Fine and colleagues[50] found the most sensitive clinical sign of myocarditis to be a soft S_1 at the apex. A prolonged PR interval, which may be a nonspecific finding in many febrile illnesses, also can cause a soft S_1, however, without any other evidence of myocarditis.[156] A high-pitched systolic murmur of mitral insufficiency is heard in some cases. The breath sounds are harsh. Scattered rhonchi and, occasionally, fine crepitations in the lung bases may be detected.

Almost uniformly, the liver is enlarged; edema is a rare finding. Some infants are less distressed and have signs of only mild congestive cardiac failure, without the signs of peripheral circulatory failure. Other infants have no signs of cardiac compromise, and myocarditis is recognized only as part of a generalized illness by a disturbance in the ECG pattern.

DIAGNOSIS

Clinical Characteristics and Radiographic Evidence

Myocarditis often is difficult to diagnose, but it should be suspected in any infant or child who presents with congestive heart failure and who has or recently had a febrile illness. The history should include information regarding travel, exposure to tuberculosis, recent drug ingestion, and illnesses in other family members or schoolmates. A quiet precordium in the presence of a gallop rhythm and decreased intensity or muffling of the heart sounds are findings that strongly suggest the diagnosis. A tachycardia out of proportion to the level of fever also should be viewed with suspicion. A physiologic S_3 is a common finding in normal healthy children and in children with anemia and fever. Sometimes, as with fever and associated tachycardia, the cardiac rhythm may have a gallop cadence. In association with it, however, the precordium is hyperactive and the heart sounds are crisp and have increased intensity. An unusually prominent S_3 suggests a disturbance of ventricular compliance without other evidence of compromised cardiac function and should be investigated further with an echocardiogram, a chest radiograph, and an ECG.

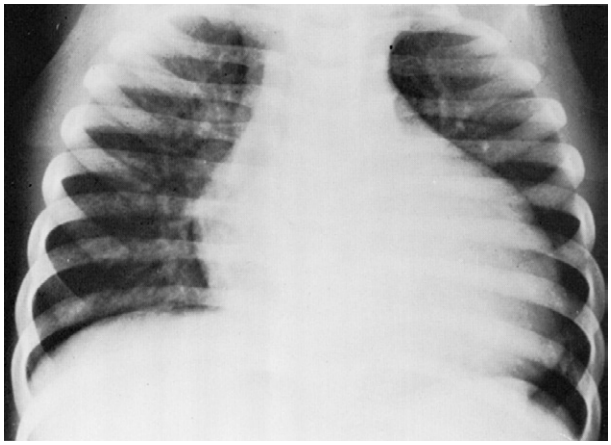

FIGURE 28-8 ■ Marked cardiomegaly with a mild increase in the pulmonary venous pattern in the upper lobes.

Chest radiographs of infants and children who have signs of congestive cardiac failure invariably show cardiomegaly, usually of a severe degree (Fig. 28-8). All four chambers may be enlarged, and evidence of pulmonary venous congestion often is found.

Sometimes, especially in newborns, the first sign of illness is acute circulatory collapse, and, in this circumstance, the cardiac size may be normal. The same is true of children who have an arrhythmia rather than congestive heart failure. Other patients may present with Stokes-Adams attacks caused by complete heart block.[101]

The occurrence of an arrhythmia, especially after a febrile illness, should alert the clinician to look for other signs of myocarditis.[32,159] Lind and Hulquist[102] detected significant dysrhythmias in five infants with isolated myocarditis. Four of the five infants died, and three of these infants had paroxysmal atrial tachycardia. Paroxysmal atrial tachycardia has been reported in patients with viral myocarditis[32,159] and has been described in patients with diphtheritic myocarditis.[15] Atrial ectopic tachycardia may mimic sinus tachycardia and, if not carefully evaluated, may be the primary cause for significant myocardial dysfunction. Complete heart block has been described in children in association with acute idiopathic myocarditis[83,101] and with rubella,[105] coxsackievirus,[153] and respiratory syncytial virus[12,59] infections. In some instances, complete heart block is permanent, and in others, it is temporary.[12,60,83] The ECG is an essential diagnostic tool for all patients with suspected myocarditis.

The classic ECG pattern in myocarditis is one of diffuse low-voltage QRS complexes (<5 mm total amplitude) with low-amplitude or slightly inverted T waves and a small or absent Q wave in leads V_5 and V_6 (Fig. 28-9). The low-voltage signal may be present in the standard leads and the precordial leads. Figure 28-10 shows the ECG of an infant with acute myocarditis and shows a pattern of acute myocardial ischemia. Figure 28-11A shows multifocal extrasystoles and severe intraventricular conduction delay in a patient with diphtheritic

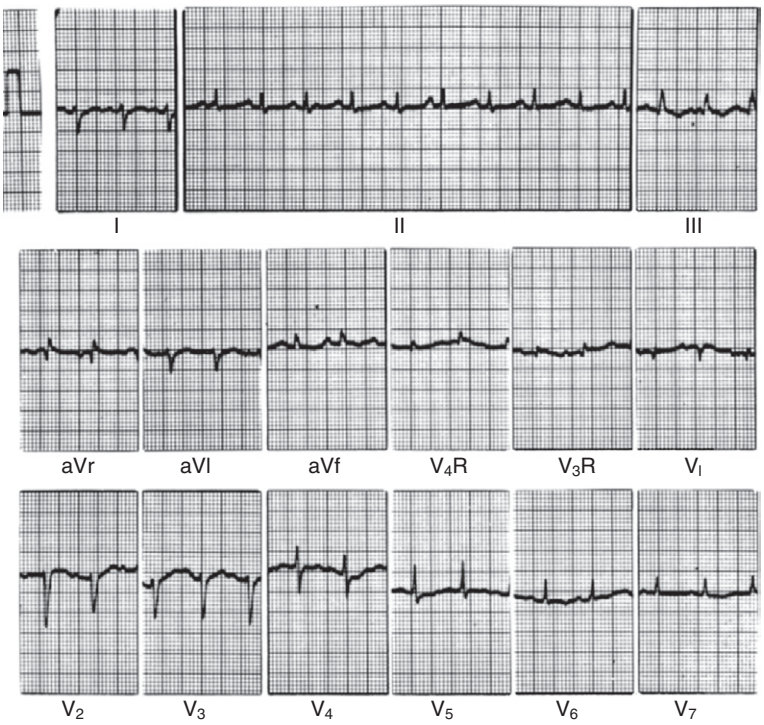

FIGURE 28-9 ■ Diffuse low-voltage or QRS complexes with T-wave flattening and 1-mm Q waves in the lateral precordial leads represents the classic pattern in myocarditis.

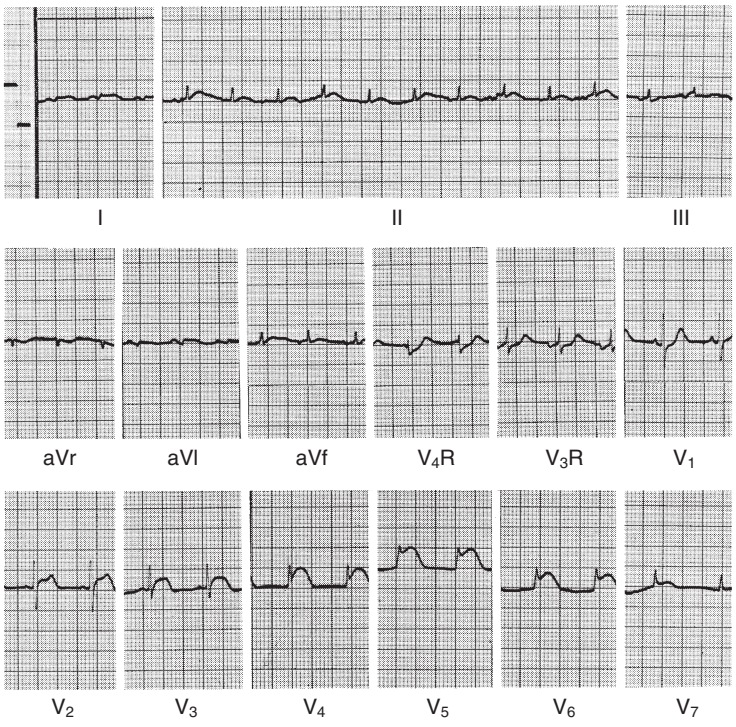

FIGURE 28-10 ■ In addition to low voltage, there is evidence of acute myocardial ischemia with 4- to 5-mm ST-segment elevation dominantly in the middle and lateral precordial leads.

myocarditis; the ECG of this child returned to normal over the course of 3 months (see Fig. 28-11B). The ECG from a 5-month-old infant who had mild fever, diarrhea, and vomiting for 3 to 4 days before admission is shown in Figure 28-12. The 2 : 1 atrioventricular block was associated with normal QRS complexes. This abnormality persisted in the absence of clinical symptoms for 1 year. Figure 28-13 shows a left bundle branch block that was identified in a 10-month-old infant with acute idiopathic myocarditis. Anomalous origin of the left coronary artery from the pulmonary artery was suspected but was excluded by catheterization. This ECG pattern persisted for at least 6 months.

Karjalainen and colleagues[85] studied the ECGs of 87 conscripts between 18 and 30 years old, 28 of whom had myocarditis. The most frequent findings were T-wave changes of reduced amplitude or inversion in the left chest leads. Sinus tachycardia followed by premature

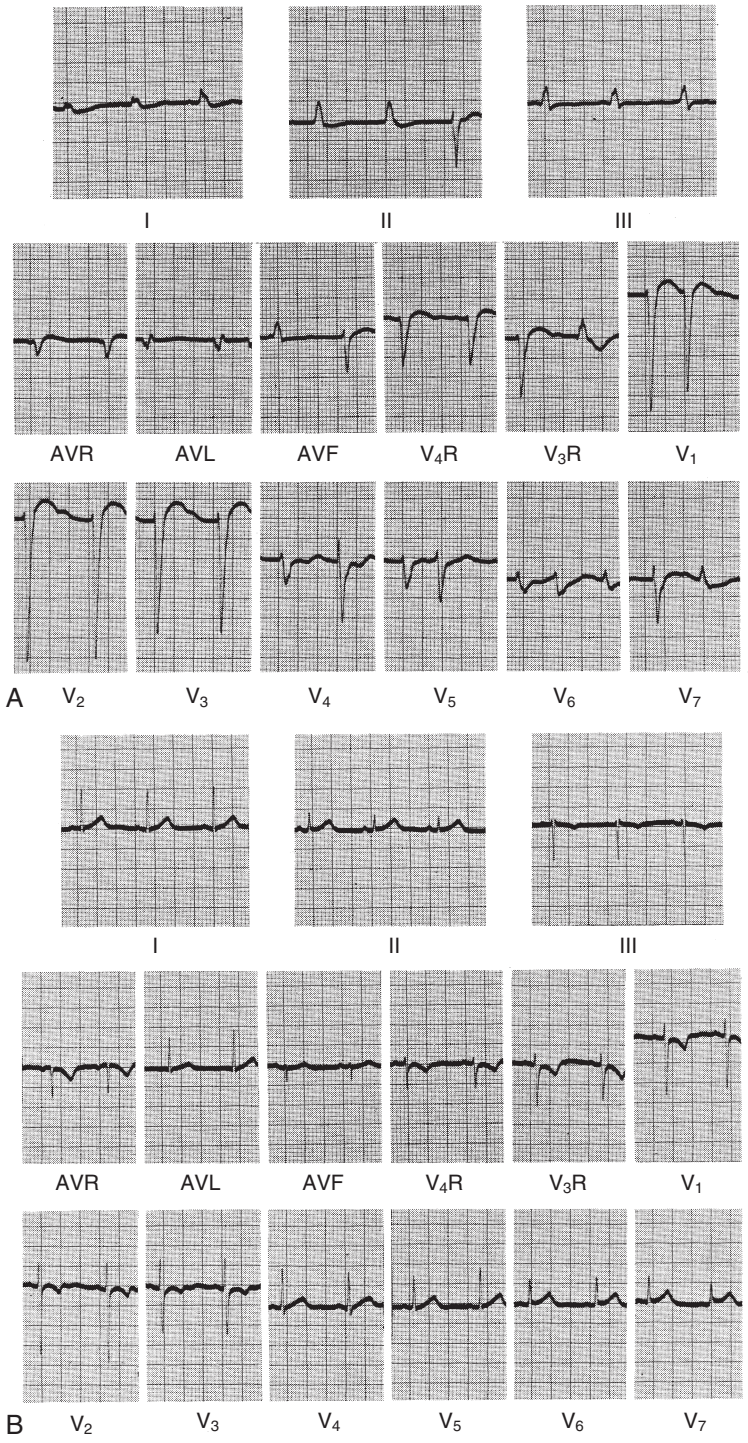

FIGURE 28-11 ■ **A,** Multifocal premature beats are caused by atrioventricular dissociation and left bundle branch block resulting from diphtheritic myocarditis. **B,** A normal electrocardiogram is shown for the same patient 3 months after an episode of myocarditis.

ventricular depolarizations was the most common dysrhythmia. Take and colleagues[165] examined serial ECGs of 16 patients with confirmed viral myocarditis. They found four patterns: (1) complete normalization in the presence of severe myocardial damage in the acute stage; (2) "pseudoinfarction" patterns with Q waves and poor R-wave progression; (3) permanent conduction disturbances that might require pacemaker support; and (4) chronic dysrhythmias, predominantly ventricular tachycardia and supraventricular tachycardia.

Although T-wave and ST-segment changes are the most sensitive indices of myocardial ischemia, they also seem to be nonspecific. Prolongation of the PR interval is another nonspecific ECG finding frequently noted in patients with febrile illnesses. Scott and colleagues[156] showed a 1.49 percent prevalence of these findings in a group of 737 infants and children with respiratory tract infections, but they also found a similar incidence among 108 control children without respiratory infection or other febrile illness. Abt and Vinnecour[1] recorded PR

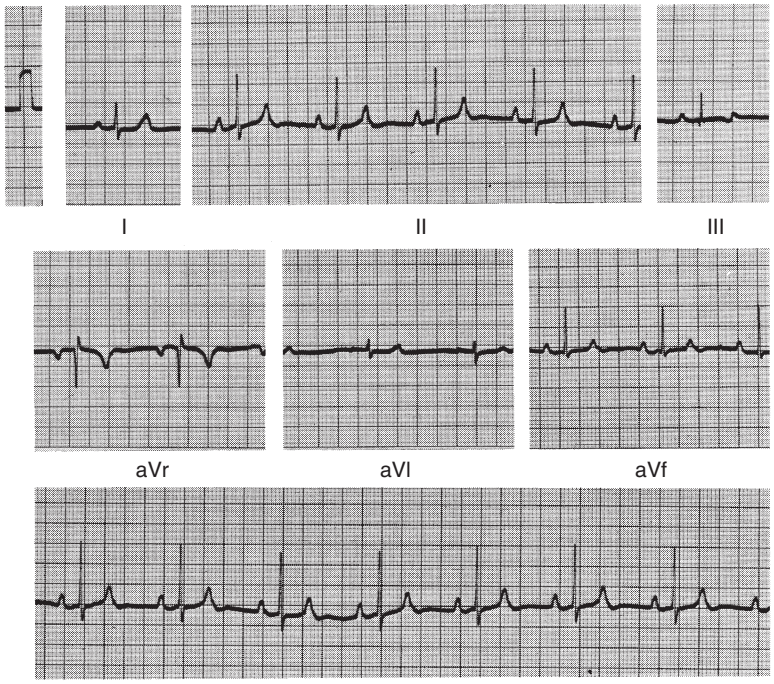

FIGURE 28-12 ■ Second-degree atrioventricular block with an effective ventricular rate of 60 beats/min. The blocked P wave is placed on top of the T wave in each cycle.

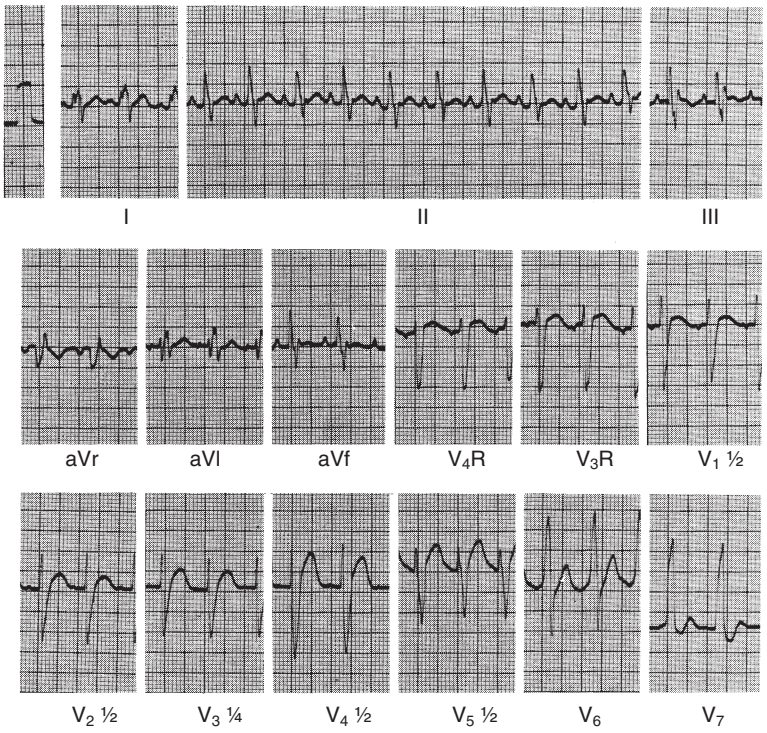

FIGURE 28-13 ■ Sinus tachycardia (rate 150 beats/min) and left bundle branch block.

prolongation and T-wave changes in infants and children who were suffering from pneumonia without other signs of myocarditis. The QT interval has been prolonged in cases of acute myocarditis, but it also appears to be a rather nonspecific finding associated with other infectious diseases.[84,146] A diagnosis of myocarditis cannot be established with certainty on the basis of these nonspecific changes.

Noninvasive diagnostic myocardial imaging techniques that are useful in the detection of myocarditis include echocardiography and magnetic resonance imaging (MRI). Echocardiography is currently recommended in the initial diagnostic evaluation of all patients with suspected myocarditis.[148] The echocardiogram is useful in assessing ventricular function and helps exclude pericardial effusion as the cause of the cardiomegaly.

Cardiovascular MRI is a safe, noninvasive technique that can be used to assess myocardial function and tissue damage in suspected myocarditis. In particular, cardiac MRI can be used to differentiate between acute and chronic myocarditis and can be used for long-term follow-up without the use of radioactive tracers or radiation. Gagliardi et al.[56] reported the first case series on the use of cardiac MRI for the diagnosis of acute myocarditis in 11 infants and children. The authors reported 100 percent specificity and 100 percent sensitivity for T-2 weighted spin echo cardiac MRI sequences in contrast to endocardial biopsy. Cardiac MRI may be a good tool for selecting patients for endomyocardial biopsy.

Endomyocardial biopsy used for establishing the diagnosis of myocarditis and possibly classifying the phase (i.e., active, healing, or healed) of viral infection may have a direct impact on the type of therapy employed. Classification of myocarditis based on histologic evidence found on biopsy specimens has proved to be a difficult and sometimes controversial task. No widespread agreement exists on the criteria for establishing the diagnosis of myocarditis from biopsy samples. Sampling error resulting from the small amounts of tissue obtained, the focal nature of sampling, and the disease process may lead to misdiagnosis. Samples usually are obtained from the right ventricular septum or apex and should contain at least three and optimally five pieces of tissue. Some investigators have found sampling from other areas of the heart (e.g., left ventricle) to be more sensitive,[173] but these techniques have not been applied widely.

Cases of "borderline myocarditis" (i.e., specimens containing increased numbers of inflammatory cells, but without evidence of myocyte necrosis) may require a repeat biopsy to confirm the diagnosis. Dec and colleagues[37] confirmed the diagnosis of myocarditis in four of six patients with an initial diagnosis of borderline myocarditis. These investigators did not show any significant advantage to sampling the left ventricle during the repeat study. Overinterpretation or misinterpretation has been cited as a major problem in the reading of biopsy specimens. Edwards and associates[46] looked at 170 endomyocardial biopsy samples and found that more than five lymphocytes per high-power field were consistent with a diagnosis of active lymphocytic myocarditis.

Using endomyocardial biopsy, Fenoglio and coworkers[49] diagnosed myocarditis in 34 patients presenting with congestive heart failure of unknown origin. They classified these patients on the basis of clinical and histologic findings in an attempt to establish subgroups of patients who might benefit from immunosuppressive therapy. Three groups were established—acute, rapidly progressive, and chronic. Immunosuppressive therapy was thought to be significantly beneficial for the last group only in terms of clinical improvement.

Dec and colleagues[38] studied 27 patients referred for endomyocardial biopsy because of congestive heart failure of unknown origin. Two thirds of the patients had biopsy samples read as positive for myocarditis, but in contrast to the study of Fenoglio and coworkers,[49] in which the histologic grouping was slightly different, no correlation was found between histologic classification and outcome. Outcome did not differ between the group receiving immunosuppressives and the group not receiving immunosuppressives. Biopsy results were negative for 30 percent of the patients who already met all the clinical criteria of myocarditis and were positive for two of five patients without any clinical evidence of myocarditis (i.e., viral-like illness, pericarditis, or laboratory evidence of viral infection).

Olsen[131] reviewed 1200 biopsy specimens from patients with a clinical diagnosis of idiopathic dilated cardiomyopathy and found that slightly more than 25 percent had a diagnosis of myocarditis established on the basis of critical evaluation of their tissue specimens. In clinical practice, endomyocardial biopsy should be used in those scenarios in which the incremental prognostic and therapeutic information gained from biopsy outweighs the risks. No large study of pediatric patients has been conducted to confirm this finding in the young.

Most physicians would agree that many cases of idiopathic dilated cardiomyopathy probably are the sequelae of unrecognized acute viral myocarditis. The role of endomyocardial biopsy in attempting to salvage patients by selecting them for specific therapy has some validity. The hope is that early intervention in some patients guided by this technique would prevent them from progressing to needing transplantation or to death from intractable heart failure.

Molecular Diagnostic Studies

Polymerase Chain Reaction

Jin and associates[82] first described the usefulness of PCR in identifying the viral genome in myocardial samples obtained from patients with suspected myocarditis. Using reverse-transcription PCR, which employs RNA to amplify the corresponding complementary DNA before final DNA amplification, the researchers were able to identify an enteroviral genome from cardiac tissue samples. Patients with dilated cardiomyopathy were shown to harbor an enteroviral genome within myocardial specimens. Confirmation of the utility of PCR in the etiologic diagnosis of a viral genome in patients with clinical myocarditis and idiopathic dilated cardiomyopathy quickly followed.* Controversy existed, however, because reports of high levels of false-positive results,[45] contamination,[31] and low sensitivity[179] were published. The strength of this rapid (<5 hours) and powerful method of amplification of a specific viral genome is also its weakness. The method depends on the quality and quantity of nucleic acid extraction, but contamination may be commonplace in some laboratories. If any requirements are altered, amplification may not occur, leading to false-negative or false-positive (i.e., contamination) results.

Numerous publications have shown that PCR is a rapid and sensitive method for establishing the diagnosis of enteroviral myocarditis and that it is probably the test of choice in the diagnosis of all virus-induced cardiac disease. Towbin and colleagues[172] used PCR to diagnose adenoviral myocarditis in a fetus with nonimmune

*References 31, 45, 63, 73, 125, 141, 177.

hydrops fetalis. In this case, the adenoviral genome was amplified from fetal blood and maternal blood at 29 weeks gestation and again at delivery at 34 weeks gestation using blood from the infant and mother and placental specimens. Using viral primers designed to amplify enterovirus, adenovirus, CMV, and HSV nucleic acid, Martin and associates[110] reported 34 patients with suspected acute myocarditis, for whom 68 percent of samples analyzed were PCR-positive. In this report, samples from 17 control patients were PCR-negative. Adenovirus was the most common viral genome identified (58%), and enteroviruses were the second most common (29%). A few reported cases were PCR-positive for HSV and CMV.

Lozinski and coworkers[106] confirmed the importance of adenovirus in their study of cases of myocarditis for which no cause had been found previously; in this case, 66 percent of the previously unidentified cases were identified as adenovirus. In a more recent study by Bowles and colleagues,[23] viral genomes were detected in 20 percent of 149 patients with the diagnosis of dilated cardiomyopathy. In these patients, adenovirus was identified in 12 percent and enterovirus in 8 percent of dilated cardiomyopathy cases. In all age groups, adenovirus and enterovirus were the viruses most commonly detected in acute myocarditis and dilated cardiomyopathy.

Schowengerdt and colleagues[155] showed that a variety of viruses might be the inciting cause of rejection in patients after undergoing heart transplantation. Using PCR of endomyocardial biopsy specimens, the investigators showed a direct correlation between histologic rejection and PCR-positive viral study results. Studying patients undergoing serial endomyocardial biopsies, they found that the viral genome could be amplified in transplant-rejecting patients who previously had negative PCR analyses. In these cases, as the rejection grade improved, the PCR results again became negative. The most common viruses correlated with rejection were adenoviruses, CMV, and parvovirus. The researchers postulated that this form of rejection probably is another form of myocarditis, and this hypothesis has been supported by other clinical studies.[178]

Virologic and Bacteriologic Studies

For each infant or child with a diagnosis of acute myocarditis, an attempt should be made to identify the offending organism. If the patient is seen early in the illness, isolation of the virus from throat washings, stool, blood, or the myocardium may be possible.

Lerner and colleagues[98] suggested criteria that would help define an etiologic association between a coxsackievirus infection and myocarditis. High-order associations included isolation of the virus from the myocardium, the endocardium, or pericardial fluid and localization of type-specific virus in myocardium, endocardium, or pericardium at sites of pathologic change.

Moderate-order associations are determined when virus is isolated from pharynx or feces, and a fourfold increase in type-specific, neutralizing, hemagglutination-inhibiting, or complement-fixing antibodies is shown, or when virus is isolated from pharynx or feces with a concurrent serum titer of 1 : 32 or greater of type-specific, IgM-neutralizing or hemagglutination-inhibiting antibodies. In chronic illness, attempts at virologic identification are less fruitful.[65] Blood for aerobic and anaerobic cultures should be obtained from any infant with fever and signs of compromised cardiovascular function.

Serum Biomarkers

In the setting of acute myocarditis, increased levels of creatine kinase and troponin indicate inflammatory myocardial injury. However, limited myocardial necrosis during myocarditis may contribute to the limited prevalence of elevated troponin T values in biopsy-proven myocarditis cases. Although most available studies involve adult patients, it is acknowledged that cardiospecific troponins provide evidence of myocyte injury in patients with myocarditis more sensitively than do conventional cardiac enzymes. The sensitivity of cardiac biomarkers of myocardial injury varies depending on the time from symptom onset to testing and the cutoff values used. In pediatric patients with acute myocarditis, the sensitivity and specificity of troponin T were 75 and 75 percent when the cutoff was set at 0.026 ng/mL and 63 and 89 percent with a cutoff value of 0.071 ng/mL.[157] In contrast to creatine kinase activities, troponin T also provides improved sensitivity for detection of micronecrosis because of a proportionally higher and longer-lasting increase in the blood.[157] The erythrocyte sedimentation rate, C-reactive protein, and leukocyte count may be elevated, but these are considered nonspecific.

DIFFERENTIAL DIAGNOSIS

Any cause of circulatory failure, especially when acute in onset, may mimic myocarditis. In newborns, heart failure associated with hypoxia, hypoglycemia, and hypocalcemia is well recognized, whereas circulatory collapse may occur with any infection and without direct involvement of the myocardium. A careful history may help elucidate possible precipitating factors. Biochemical investigations to exclude hypoglycemia and hypocalcemia always should be conducted in any newborn with signs of heart failure. Blood cultures should be obtained when infection is suspected.

Many infants with structural cardiac defects (e.g., hypoplastic left heart syndrome, aortic valve stenosis) may not have audible murmurs when severely ill. Murmurs usually appear, however, with treatment and improvement in cardiac function. The precordium usually is hyperactive, rather than quiet, and the heart sounds are clear and increased in intensity, rather than muffled. The ECG usually shows severe right ventricular hypertrophy in the former condition and right ventricular or left ventricular hypertrophy in the latter; the ECG is useful in the differential diagnosis. The findings on an echocardiogram often are diagnostic.

Beyond the immediate neonatal period, the major disease entities that require differentiation from myocarditis are endocardial fibroelastosis, anomalous left coronary artery arising from the pulmonary artery, Cori type

II glycogen storage disease (i.e., Pompe disease), medial necrosis of the coronary arteries, left atrial myxoma,[126] and other congestive cardiomyopathies of undetermined cause.

Common to all of these disorders is moderate to severe cardiomegaly, usually associated with congestive cardiac failure, gallop rhythm, and the infrequent occurrence or absence of murmurs. The murmurs are associated primarily with an anomalous left coronary artery and endocardial fibroelastosis. They are not more than grade 3/6 in intensity, are high-pitched, are apically located, and represent some degree of mitral insufficiency. Idiopathic myocarditis occurs primarily in patients older than 6 months of age,[144,145] whereas most of the conditions described earlier manifest before the infant is 6 months old.

Endocardial fibroelastosis, a common cause of congestive cardiac failure in infants, is impossible to differentiate from acute myocarditis on the basis of clinical examination alone. An anomalous origin of the left coronary artery should be identified. The ECG usually shows left axis deviation of the QRS complex in the frontal plane, left ventricular hypertrophy, and a pattern of anterolateral myocardial infarction. It is recognized as a QR pattern with inverted T waves in standard leads I and aV_L, a broad Q wave with inverted T waves in precordial leads V_5 and V_6, and loss of anterior forces in the mid-precordial leads. For definitive diagnosis, cardiac catheterization is essential.

Pericarditis, frequently caused by viruses, usually occurs in children rather than in infants. The clinical history may be identical to that of patients with myocarditis; however, considering the degree of cardiomegaly, cardiovascular function is compromised less than in patients with myocarditis, although cardiac tamponade may occur in some cases. Differentiation from myocarditis may be made clinically if the patient has a friction rub, no gallop rhythm, and a typical pattern of chest pain. Further studies may be required, however, to make a conclusive diagnosis. The echocardiogram is invaluable in establishing this diagnosis. It is the most sensitive and least traumatic technique available and easily identifies an effusion. Myocarditis and pericarditis may occur together. This combination is seen most frequently in the pancarditis of rheumatic fever, but it also may occur in coxsackievirus B infections and in many collagen vascular and autoimmune diseases. Myocarditis has been associated with rheumatoid arthritis,[119] systemic lupus erythematosus,[40] and ulcerative colitis.[51,124]

TREATMENT

Standard Approaches

Intensive medical care is required during the acute stage of the illness. Heart rate, respiratory rate, and blood pressure should be monitored frequently, and a careful assessment of urine output and fluid intake is mandatory. All patients require bed rest. Experimental studies in mice have shown that exercise increases replication of virus in the myocardium and increases the mortality rate from myocarditis by 100 percent.[57] Although extrapolating directly from experimental studies in animals to the human situation always is dangerous, suggesting strict bed rest during the early stages of acute myocarditis seems to be a prudent measure. For infants or children with signs of congestive cardiac failure or shock, oxygen should be administered to maintain a normal arterial blood oxygen tension.

No specific therapeutic modality is known that can reverse the myocardial injury directly, but much can be done to maintain adequate tissue perfusion, prevent metabolic disturbances, and support myocardial function. When congestive cardiac failure is identified, digitalis should be administered. This agent should be used with caution, given the increased expression of proinflammatory cytokine and increased mortality rates observed in murine myocarditis treated with high-dose digitalis.[115,116] Diuretics also are used frequently to treat cardiac failure. Diuretics have no direct beneficial effect on the myocardium; they should be used cautiously because rapid reduction in extracellular fluid volume may lead to shock, and the loss of potassium associated with vigorous diuresis may precipitate digitalis toxicity. The frequency of administration depends on the clinical state of the patient.

In some instances, especially in newborns, the primary presentation may be shock. The blood pressure usually is maintained close to normal levels until late in the course of disease; it cannot be a reliable index of the severity of the patient's condition. Cold extremities, increasing heart rate, and low urine output are much more sensitive indicators of a reduction in effective circulating blood volume. Although the hearts of these infants and children respond poorly to volume loading, a colloid transfusion may help in selected patients. Albumin as a 5 percent solution in lactated Ringer solution or whole blood may be administered.

If the patient remains in shock despite administration of these high filling pressures, a positive inotropic agent is required. Dopamine exerts an inotropic effect on the heart and concomitantly dilates the renal vessels, improving urine output. The usual dose is 2 to 10 μg/kg/min. As the dose increases to 20 μg/kg/min, dopamine has a more dominant α-adrenergic effect and may increase systemic peripheral resistance; experts avoid doses greater than 15 μg/kg/min. Dobutamine, which is a sympathomimetic amine that stimulates β_1-adrenergic, β_2-adrenergic, and α-adrenergic receptors, may be useful in combination with dopamine. It has significant inotropic activity while decreasing left ventricular filling pressure. Dobutamine does not induce the positive chronotropic effect and increased ventricular irritability that are seen with dopamine. Used in combination with low doses of dopamine (<10 μg/kg/min), dobutamine (in doses ≤10 μg/kg/min) may result in significant positive inotropism, while preventing a sinus tachycardia that may compromise cardiac output further.

Isoproterenol, a commonly used inotropic agent, should be avoided because it causes a significant increase in heart rate and may affect cardiac function adversely. When these drugs are used, ensuring normal acid-base balance is important because action of the agents is decreased significantly by acidosis.

Sodium nitroprusside, phentolamine, and the nitrates have been used in adults. These agents have been used less extensively in children, primarily in the early postoperative period after open heart surgery, to improve cardiac function. They improve cardiac output by indirectly reducing systemic arterial resistance, venous filling pressure, or both. One study showed a marked improvement in the reduction of inflammation, necrosis, and dystrophic calcification in mice infected with coxsackievirus B3 when they were treated with captopril, an angiotensin-converting enzyme inhibitor, early after development of infection.[143] They improve cardiac output by indirectly reducing systemic arterial resistance or venous filling pressure, or both. One study showed a marked improvement in the reduction of inflammation, necrosis, and dystrophic calcification in mice infected with coxsackievirus B3 when they were treated with captopril, an angiotensin-converting enzyme inhibitor, early after development of infection.

A temporary pacing catheter should be inserted when complete heart block occurs. In many instances, the temporary pacing catheter allows time for spontaneous recovery of atrioventricular conduction. A permanent pacemaker may be required; if so, it should be inserted as an elective, rather than emergency, procedure. Only a demand pacemaker should be used because in most instances a return to normal rhythm is expected; use of this type of pacemaker avoids the risk for competition between the patient's inherent rhythm and the pacemaker, as would occur with a fixed-rate device. If infants or children experience Stokes-Adams attacks, a transthoracic pacing wire may have to be inserted as an emergency procedure.

Antibiotics should not be given routinely, unless a bacterial infection is suspected. Appropriate cultures need to be obtained before use of antibiotics.

Immune Modulating Agents

The use of immunosuppressive agents in the treatment of viral or suspected viral myocarditis is controversial. Immunosuppressant therapy in animal models of viral myocarditis has not been shown to be beneficial. One reason for the lack of efficacy of immunosuppressant therapies may relate to the duality of the effects of the immune system. Corticosteroids enhanced viral titers in the early phase of viral murine myocarditis, whereas cyclosporine caused greater mortality and cardiac insufficiency in EMCV myocarditis.[120,171] The use of immunosuppressive agents in the treatment of viral or suspected viral myocarditis is controversial. Immunosuppressant therapy in animal models of viral myocarditis has not been shown to be beneficial. One reason for the lack of efficacy of immunosuppressant therapies may relate to the duality of the effects of the immune system. Corticosteroids enhanced viral titers in the early phase of viral murine myocarditis, whereas cyclosporine caused greater mortality and cardiac insufficiency in EMCV myocarditis.[88,89] A report of 13 children with biopsy-confirmed myocarditis treated with prednisone approximately 3 weeks after symptoms occurred showed a marked reduction in inflammation on the follow-up biopsy specimen.[30] This study was uncontrolled, however, and may not truly represent an accurate account of the role of immunosuppressive therapy.

Mason and colleagues[112] used endomyocardial biopsy as a means of diagnosing and following the effects of immunosuppressive therapy in 10 patients. Eight patients received a combination of prednisone and azathioprine, and two patients received prednisone alone. Four patients improved clinically and histologically while on therapy. Two patients who had medications discontinued had relapses, which were reversed with reinstitution of therapy. Only one patient worsened while on therapy, and that patient died. Although the study by Mason and colleagues[112] was uncontrolled, the reversal of congestive heart failure seen in the two patients who were restarted on therapy suggests the beneficial effect of these agents.

Kereiakes and Parmley[86] tabulated most of the studies showing the effects of immunosuppressive therapy in patients with myocarditis. Sixty percent of 82 biopsy-confirmed cases of myocarditis showed improvement with steroids alone or in combination with azathioprine. Patients with lower grade inflammatory changes seem to do better than patients with higher grade changes. Complications of immunosuppressive therapy, including opportunistic infections and a cushingoid state, have been reported and may limit the amount and type of therapy.[112,163]

Hobbs and associates[74] used combined prednisone and azathioprine to treat 34 adults with biopsy-confirmed myocarditis. Survival was no better for patients with histologic improvement than for patients with persistent infiltrates. Most patients experienced side effects, some of them lethal, from the corticosteroids. The potential benefits of this type of therapy must be weighed against the risk for immunosuppression in each patient with myocarditis. This therapy apparently does not prevent the observed ECG changes seen in untreated patients or the associated neuritis.[169]

Although numerous anecdotal and small case series suggested that patients with viral myocarditis might benefit from early steroid or immunosuppressive therapy, the results of the Myocarditis Treatment Trial suggested that treating patients who received a histopathologic diagnosis of myocarditis with immunosuppressive therapy for 24 weeks (prednisone plus cyclosporine or prednisone plus azathioprine) did not lead to an improvement in ejection fraction in contrast to conventional therapy.[113] The major limitation of this study was the unexpectedly low rate of positive biopsy specimens (<10%) and the extension of enrollment to 2 years after the initial clinical presentation. For many patients, the disease possibly already had progressed from ongoing immune-mediated cardiac injury to dilated cardiomyopathy, and any form of therapy may have been ineffective in this setting. Frustaci and colleagues[54] reported a favorable treatment response in adult patients with chronic active myocarditis. Of 43 patients (88%) on immunosuppressive therapy (prednisone 1 mg/kg/day for 4 weeks followed by 0.33 mg/kg/day for 5 months and azathioprine 2 mg/kg/day for 6 months), 38 showed an improvement in cardiac function and dimensions, defined as an increase of more

than 10 percentage points in the absolute ejection fraction and a reduction of left ventricular end-diastolic volume. None of the untreated patients showed improvement in cardiac function. Immunosuppressive therapy in adult patients with biopsy-proven, virus-negative inflammatory cardiomyopathy may be an effective and safe option in addition to supportive treatment for cardiac failure.

Data regarding the efficacy of immunosuppressive therapy for myocarditis in children are limited. Accordingly, routine immunosuppressive therapy is no longer recommended for pediatric myocarditis patients with a stable clinical course. However, many clinicians still recommend aggressive immunosuppressive therapy for patients with fulminant myocarditis or a deteriorating clinical course.

Various immunomodulatory therapies have been proposed for the autoimmune phase of viral myocarditis. Kishimoto and colleagues[93] found that immunoglobulin therapy suppressed coxsackievirus B3–induced murine myocarditis and increased survival in C3H/He mice after infection with EMCV. Intravenous immunoglobulin (IVIG) therapy reduced various proinflammatory markers, including TNF, IFN-γ, macrophage inflammatory protein–2, interleukin-6, plasma catecholamines, and soluble intercellular adhesion molecule–1.[93] Exogenous immunoglobulins modulate diverse immune response mechanisms; however, the exact mechanism by which IVIG modifies myocarditis remains to be determined. Drucker and associates,[43] who investigated the use of IVIG in 21 of 46 children with myocarditis, showed that patients who received this drug had better left ventricular function at follow-up. Survival tended to be higher at 1 year, although the data did not reach statistical significance because of the small number of patients in the study. More recently, in a prospective placebo-controlled trial with IVIG in adult patients with recent-onset dilated cardiomyopathy or myocarditis, treatment with IVIG did not result in an improvement in left ventricular function compared with placebo-treated patients.[117] Kim and colleagues[90] retrospectively assessed the effects of IVIG therapy in pediatric patients with presumed myocarditis on survival and recovery of ventricular function. These patients were divided into two groups. Group 1 consisted of 23 patients (69.6%) who received IVIG alone or IVIG in combination with steroids, and group 2 consisted of 10 patients (30.3%) who received neither IVIG nor other immunosuppressive agents. One year after the initial presentation, no difference was seen between the IVIG-treated patients and the control patients in the degree of recovery of left ventricular function and survival. Although no randomized controlled trials of IVIG for the treatment of myocarditis in children have been reported, some clinical evidence suggests it may be beneficial.

IFN-β serves as a natural defense against many viral infections. Its innate production is associated with clinical recovery from viral infection and subsequent sequelae, whereas exogenous administration may be protective. Studies have suggested that IFN-β may have a role in the treatment of chronic viral cardiomyopathy. Kuhl and colleagues[95] reported that patients with persistent enterovirus and adenovirus infections of the myocardium responded well to a 6-month course of IFN-β1a. Follow-up biopsies taken 3 months after completion of treatment showed complete elimination of enteroviral and adenoviral genomes. Virus clearance was associated with improvement of mean left ventricular function, a decrease in ventricular size, improvement of heart failure symptoms, and a decrease of infiltrating inflammatory cells. Patients with severely affected left ventricular dysfunction experienced the greatest improvement. Additional studies have shown that parvovirus B19 responds less well to IFN-β treatment with respect to virus clearance and hemodynamic changes.[154] Treated patients, however, do show some clinical improvement despite incomplete virus clearance. Data regarding the use of IFN-β therapy for myocarditis in children are not available.

PROGNOSIS

The prognosis of acute myocarditis caused by coxsackievirus B infection in a newborn is poor. Kibrick and Benirschke[87] reported a 75 percent mortality rate among 25 infants with coxsackievirus B myocarditis. The greatest number of deaths occurred in the first week of the illness. No apparent sequelae occurred in the six infants who survived, although no long-term follow-up data were available. The outlook in other infants and children with clinically recognized myocarditis is better, but mortality rates remain significant (10% to 25%). Hastreiter and Miller[71] observed complete recovery in 50 percent of patients. Another 25 percent became asymptomatic, but abnormal ECGs or chest radiographs persisted. An abnormality may not be evident on the ECG unless the patients are exercised.[16] Despite lack of symptoms, many adult patients have a reduced working capacity associated with exercise stress testing.[18]

The outcome of myocarditis is related partly to the cause. Patients with diphtheritic myocarditis who have arrhythmias or conduction abnormalities have a very poor prognosis. Tahernia[164] found in his study that all patients with disturbances of conduction died. Begg[15] also reported a 100 percent mortality rate for patients with diphtheritic myocarditis who developed supraventricular tachycardia.

Chronic arrhythmias may persist long after the acute disease has passed. Friedman and colleagues[52] performed a retrospective analysis of 12 patients with biopsy-confirmed myocarditis and complex ventricular arrhythmias at the time of presentation (11 with ventricular tachycardia). Of the 12 patients, 5 were still receiving antiarrhythmic therapy at a median follow-up of 50 months. Complex ventricular arrhythmias were still present in these patients (3 with ventricular tachycardia and 2 with couplets or multiforms), requiring ongoing therapy. The investigators concluded that although the arrhythmias were controlled more easily than at presentation of the patients, ongoing surveillance was essential in ensuring the suppression of these potentially life-threatening arrhythmias. Children who recover from myocarditis, regardless of cause, should be followed indefinitely.

MYOCARDITIS IN CASES OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Infection with human immunodeficiency virus (HIV) may affect the heart adversely. Cardiac dysfunction, including congestive heart failure, may occur; many patients who have died and undergone autopsy are shown to have myocarditis. Anderson and associates[5] retrospectively analyzed 71 consecutive necropsy patients who died of acquired immunodeficiency syndrome (AIDS) and found that 52 percent had evidence of myocarditis. Opportunistic agents could account for only a few of the cases, and most were considered idiopathic.

Another study examined autopsy specimens of 26 consecutive cases. Lymphocytic myocarditis was seen in nine patients (35%), and another seven patients had lymphocytic infiltrates without myocytolysis.[14] Acierno[2] correctly pointed out that a distinction must be made between AIDS-associated myocarditis and secondary myocarditis caused by known pathogens or idiopathic myocarditis.

Reilly and colleagues[142] found a 45 percent incidence of myocarditis in 58 consecutive autopsy cases. Congestive heart failure, ventricular tachycardia, and other ECG abnormalities were seen in nearly 60 percent of the patients. Two patients died suddenly, both with myocarditis. In a prospective study of asymptomatic HIV-infected patients, the reported mean annual incidence of progression to dilated cardiomyopathy was 15.9 cases per 1000 patients. Endomyocardial biopsy specimens revealed myocardial inflammation in 63 of 76 (83%) of these high-risk patients. HIV-infected cardiac myocytes were detected by in situ hybridization in 58 of 76 (76%) patients.

In a prospective multicenter study of 205 children infected vertically with HIV enrolled at a median age of 1.9 years and 600 HIV-exposed children enrolled prenatally or as neonates, the 5-year cumulative incidence of cardiac dysfunction ranged from 18 to 39 percent in HIV-infected children.[162] Myocardial inflammation, with or without cell destruction, is a frequent finding in patients infected with HIV. Whether this response is due to the virus itself or to opportunistic agents or other toxic reactions is unclear.

Another important cause of cardiomyopathy in HIV and AIDS is drug cardiotoxicity. Zidovudine is associated with diffuse destruction of cardiac mitochondrial ultrastructure and inhibition of mitochondrial DNA replication that may contribute to myocardial cell dysfunction.[99]

The use of highly active antiretroviral therapy (HAART) regimens, by reducing the incidence of myocarditis, has reduced the prevalence of HIV-associated cardiomyopathy by about 30 percent in developed countries.[13]

PARASITIC MYOCARDITIS

Chagas Disease

Parasitic myocarditis is an uncommon form of heart disease in the United States. Chagas disease is caused by infection with *Trypanosoma cruzi*, however, and it is a long-lived infection that affects approximately 17 million individuals in Latin America.[147] This disease is endemic in Mexico and Central and South America, where vector-borne transmission of *T. cruzi* typically occurs in persons living in rural areas. Emigration from Chagas-endemic areas has changed the epidemiology of this disease in the United States and other nonendemic regions. Bern and Montgomery[20] estimated that 300,000 persons living in the United States are chronically infected with *T. cruzi*.

After inoculation, the protozoa multiply and migrate widely throughout the body. Host control of this parasite has been shown to depend on humoral and cell-mediated adaptive responses and elements of the innate immune system.[61]

Immune-mediated cardiac injury, caused primarily by infiltrating mononuclear cells, probably is the main mechanism responsible for the development of chronic Chagas heart disease. This hypothesis is supported by several observations. Animal models of *T. cruzi* infection have shown lysis of nonparasitized cardiac myocytes by immune effector cells[7]; depletion of $CD4^+$ T-lymphocyte subpopulations abrogates myocardial injury in a murine model of chronic Chagas disease; and myocardial damage can be induced in healthy animals by passive transfer of $CD4^+$ T cells from *T. cruzi*–infected mice.[41] Although $CD4^+$ T cells seem to be crucial in myocardial injury, $CD8^+$ T cells may have a protective role. Mice depleted of $CD8^+$ T cells have a robust parasitemia, but almost no inflammatory infiltrates are seen in the parasite-infected tissues.[166]

More recently, a role for TLR signaling in resistance to *T. cruzi* is suggested by the observations that mice deficient in MyD88, an adapter molecule required for signaling events by most TLRs, show enhanced susceptibility to infection with this protozoan parasite.[27] Acute Chagas disease usually is an illness of children, but it can occur at any age.[121] Histologic examination of the heart during the acute phase reveals intracellular parasites with a marked cellular infiltrate, particularly around myocytes that have ruptured and released the parasites.[135] A well-established fact is that intracellular parasites are found in cardiac myocytes only during the acute phase of illness.

Histologic examination reveals focal but widespread areas of cellular infiltrates composed of plasma cells, eosinophils, mast cells, and macrophages.[122] Extensive fibrosis occurs, replacing previously damaged myocardial tissue. In contrast to the situation observed in acute disease, the presence of parasites (a rare finding) in tissue has little correlation with myocardial pathology. Inflammatory changes in the right bundle branch and the anterior fascicle of the left bundle branch explain the frequent occurrence of right bundle branch and left anterior fascicular block.[123]

Vector-borne acute Chagas disease is usually mild, and most acute infections are subclinical. After an incubation period of 1 to 2 weeks, a newly infected individual may develop nonspecific signs and symptoms such as fever, chills, myalgias, tachycardia, rash, and meningeal irritation. A raised inflammatory lesion at the site of parasite entry (a chagoma), unilateral periorbital edema (Romaña sign), conjunctivitis, lymphadenopathy, and

hepatosplenomegaly may also be observed in acute infection.[108] The clinical manifestations of chronic Chagas disease range from isolated rhythm disturbances to advanced disease characterized by cardiomegaly, chronic congestive heart failure, and arrhythmias. Syncope also is a frequent problem of the disease. In one series of 53 patients with chronic Chagas disease, the most frequent causes of recurrent syncope were ventricular tachycardia (43%) with a poor prognosis and paroxysmal atrioventricular block (21%) with a favorable prognosis.[111] Sudden death caused by ventricular fibrillation is a constant threat and may develop before cardiomegaly or heart failure is diagnosed.[29]

Severe myocarditis develops in only a few acute cases, and most deaths are caused by the resultant congestive heart failure and pericardial effusion. Nonspecific ECG changes are seen, but the life-threatening arrhythmias that are frequent occurrences in chronic Chagas disease generally do not occur. In most patients with more acute disease (90% of cases), symptoms resolve gradually over weeks to months.

Chronic progressive Chagas disease develops in 10 to 20 percent of previously asymptomatically infected individuals.[44] It is manifested by a chronic, diffuse, progressive fibrosing myocarditis that involves the myocytes and the atrioventricular conduction system.[122,123] On gross examination, the heart usually is enlarged and flaccid. Thrombus formation frequently occurs, and thrombus may fill much of the apex of the left ventricle in some cases.

The diagnosis of acute *T. cruzi* infection in a patient is usually made by the detection of parasites in wet mounts of blood and in Giemsa-stained slides. Testing for anti–*T. cruzi* immunoglobulin M antibodies is not useful because tests for this antibody isotype are not well standardized. The diagnosis of chronic Chagas disease cannot be made solely on the basis of histologic examination of the heart. PCR testing is thought to be the most sensitive method for detecting acute *T. cruzi* infection. This test is available at the Centers for Disease Control and Prevention (CDC) in the United States.

Serologic testing is the method of choice for establishing the diagnosis of chronic Chagas disease. Several highly sensitive serologic tests for the detection of anti–*T. cruzi* antibodies, such as indirect hemagglutination, complement fixation, indirect immunofluorescence, and enzyme-linked immunosorbent assay, are available.[91,158] A radioimmunoprecipitation assay based on iodinated *T. cruzi* proteins is sensitive and specific and is currently being used for confirmatory testing of many U.S. blood donor samples that are positive in 1 of the 2 screening tests currently approved by the Food and Drug Administration (FDA) for donor screening.[108]

The treatment of Chagas disease involves both parasite-specific therapy and adjunctive therapy for the management of the clinical manifestations. Benznidazole and nifurtimox are the only available drugs with activity against *T. cruzi*. Neither drug is FDA approved, but both are available under investigational use protocols.* Although these two drugs have been thought to be ineffective or too toxic for treating chronic infections, in a recent report a 60-day course of benznidazole therapy eliminated infection in more than 60 percent of chronically infected children.[6] These drugs are most effective for the treatment of acute and congenital infection. Parasitologic cure is believed to occur in 60 to 85 percent of persons with acute infection who complete a full course of either drug, although no large-scale studies support these data. Patients with acute infections, including congenitally acquired infections in neonates, and chronically infected children should be treated. Bern and colleagues[19,21] have described the management of persons newly diagnosed with Chagas disease as a result of screening prompted by country of origin or blood donation. The antifungal agent posaconazole[136] has been used to treat a patient with chronic Chagas disease, but its overall usefulness has not been determined. A large clinical trial designed to address the efficacy of benznidazole treatment in patients with early manifestations of cardiac Chagas disease is underway.* Other ongoing clinical trials include the use of oral posaconazole in the treatment of asymptomatic chronic Chagas disease† (ClinicalTrials.gov).

Other Parasitic Causes of Myocarditis

Myocarditis is one of the most serious complications of trichinosis. The disease develops when undercooked meat contaminated with infective larvae of *Trichinella* is eaten. Myocardial invasion by *Trichinella spiralis* has been well described, but encystment within the myocardium has been reported only rarely.[92] At autopsy, the heart may be dilated and a pericardial effusion may be identified. Histologically, a prominent focal infiltrate composed of lymphocytes and eosinophils with interstitial edema and scattered hemorrhages commonly is found.[160]

Myocarditis usually is mild, with few clinical signs and symptoms. This myocarditis may range from chest pain to fatal congestive heart failure, however, and may mimic acute myocardial infarction.[33,64] The frequencies of ECG abnormalities among 154 cases of trichinellosis were determined to be 56 percent.[138] The abnormalities on ECG most frequently observed were a nonspecific ventricular repolarization disturbance (with ST-T wave changes), followed by bundle branch conduction disturbances and sinus tachycardia. Despite ECG evidence of myocardial involvement, less than 0.1 percent of patients with trichinosis die of this complication.[64]

The definitive diagnosis of trichinosis is based on the presence of the larval forms in tissue biopsy samples, usually from a large tender area such as the gastrocnemius muscle. Serologic testing is available through state laboratories and the CDC. Typically, serum antibody titers become positive during or after the third week of illness. The efficacy of mebendazole or albendazole in the treatment of myocarditis caused by *Trichinella* infection has not been evaluated adequately.

†http://ClinicalTrials.gov.

Toxocara canis, the principal cause of visceral larva migrans, is a rare cause of myocarditis. Most reported cases have occurred in children younger than 3 years of age.[35,174] Children especially are susceptible to infection with *Toxocara* because of their habit of crawling on the ground and putting objects into their mouths. The myocardial lesions noted on histologic examination have included granulomata and extensive eosinophilic infiltrates with foci of muscle necrosis. The clinical presentation may be acute respiratory distress caused by congestive heart failure, requiring administration of oxygen and diuretic therapy. Asymptomatic infection involving the heart also has been reported.[35]

The definitive diagnosis of *T. canis* infection requires microscopic identification of the larvae in biopsy specimens of the liver or heart, but this finding is infrequent. An enzyme immunoassay for *Toxocara* serum antibodies, which is performed at the CDC, can provide presumptive evidence of toxocariasis.

Toxoplasma gondii may cause myocarditis as part of disseminated infection or, less frequently, as an isolated cardiac infection. In infants with congenital toxoplasmosis, the clinical manifestations usually are those of meningoencephalitis, but at autopsy, extensive myocardial involvement has been documented.[190] Outside the newborn period, infection with this intracellular parasite most commonly occurs in immunosuppressed patients with malignant diseases, patients with AIDS,[28] and patients who have undergone cardiac or bone marrow transplantation.[107] Histologic examination of the heart reveals focal interstitial infiltrates consisting of histiocytes, lymphocytes, plasma cells, eosinophils, and very few polymorphonuclear cells.[168] Toxoplasma is seen as basophilic masses within a pseudocyst in normal or damaged myocardial fibers.

Clinical manifestations may include arrhythmias (atrial and ventricular), atrioventricular block, atypical chest pain, pericarditis, and heart failure. The diagnosis of toxoplasmic myocarditis requires the exclusion of other specific forms of heart disease and the establishment of evidence of toxoplasmosis with serologic testing. The diagnosis may be aided by endomyocardial biopsy.[107] Treatment with pyrimethamine and sulfonamides (especially sulfadiazine) has been reported in patients with isolated toxoplasmic myocarditis, but the response to therapy has varied. In one series of toxoplasmic myocarditis, relapses occurred in 17 percent of cases after therapy.[97]

Myocardial disease also has been reported after infection with *Echinococcus granulosus* and *Plasmodium falciparum*.[92] Cardiac involvement is estimated to occur in fewer than 2 percent of cases of echinococcosis.[39] When it does occur, the cysts usually are located in the intramyocardial region and protrude into the adjacent cardiac chambers. The clinical manifestations depend primarily on the location and size of the cyst. Rupture of the cyst is the most dreaded complication because it may lead to pericarditis, anaphylactic shock, or pulmonary emboli. Two-dimensional echocardiography is the preferred imaging study to detect and localize cysts.[130] Myocardial changes also have been documented in fatal malaria, particularly when caused by *P. falciparum*. Histologically, blocking of the coronary arteries and capillaries with parasites, local hemorrhage, and deposit of pigment occurs. Clinical findings suggestive of cardiac involvement are rare, however. In a series of 49 patients with *Falciparum* malaria, no ECG evidence of cardiac involvement was found.[161]

Myocarditis also has occurred in association with primary amebic meningoencephalitis caused by *Naegleria*. In a retrospective study, focal or diffuse myocarditis was documented in more than 40 percent of cases.[109] Myocardial involvement is not a clinically significant manifestation of this uniformly fatal central nervous system infection.

CHAPTER 29

Acute Rheumatic Fever

Diana R. Lennon

Acute rheumatic fever is an inflammatory disease of the heart, joints, central nervous system, and subcutaneous tissues that develops after a nasopharyngeal infection by one of the group A β-hemolytic streptococci. The pathogenesis of this disease, a clinical syndrome without a specific diagnostic test, remains an enigma, and specific treatment is unavailable. Prevention of initial and recurrent attacks is possible, however, with penicillin treatment and prophylaxis. Rheumatic fever is especially important because of the heart disease that often ensues, and such disease may lead to chronic progressive damage and premature death. As succinctly stated by Lasègue many years ago, "Rheumatic fever licks the joints and bites the heart"[221]—a statement that holds true today.

The unexpected upsurge in this disease in the United States in the late 1980s and 1990s, reports of invasive group A streptococcal infections, the honing of echocardiography in the diagnosis of rheumatic heart disease, and increased effort in the search for a vaccine have renewed interest in group A streptococci.

Globally, recognition that rheumatic fever is the leading cause of acquired heart disease in children and young adults worldwide led to action at the close of the century.[178] Action has intensified recently after a landmark paper suggesting the global rheumatic heart disease burden may be considerably more than previously thought.[149]

EPIDEMIOLOGY

The overall incidence and severity of acute rheumatic fever have decreased in recent years in developed Western countries and in prosperous countries of Asia.[2] Reliable morbidity data on the occurrence of acute rheumatic fever in total populations are lacking because studies often consider only a segment of a population. The trend seems clear, however. Some of the best long-term data come from Denmark, where rheumatic fever has been a reportable disease for many years.[243] A steady decline has been occurring since 1900, except for a peak during World War II (Fig. 29-1). In the United States, rheumatic fever is not a reportable disease, but mortality rates (Fig. 29-2) and hospital discharge rates (Fig. 29-3 and Table 29-1) have shown a steady decline. Although this decline was already under way, it seems to have been accelerated by the introduction of penicillin.[153]

The dramatic decline in the incidence of rheumatic fever began in the United States in the late 1940s (see Fig. 29-2). During the late 1950s, the 1960s, and the early 1970s, studies in the United States showed annual rates of 13.5 to 62.5 first attacks per 100,000 children 5 to 14 years of age; however, these studies are not strictly comparable in design.* Some of them were conducted in low-income urban areas, locations in which the incidence of rheumatic fever was thought to be higher. Secondary prevention of rheumatic fever with penicillin prophylaxis to protect against recurrent attacks probably became widespread in the 1960s. Denny and colleagues[75] showed the possibility of preventing initial attacks with injectable penicillin in 1950 in military camps after the original observation by Massell and colleagues.[159] Similar conclusive controlled studies were not repeated in the general or pediatric populations or with oral penicillin.

The most compelling evidence that appropriate medical intervention helps reduce the number of initial attacks of rheumatic fever comes from a study by Gordis[97] of health care availability in an at-risk inner-city Baltimore population. The rate of acute rheumatic fever was reduced by 60 percent over the course of a decade in only the census tracts receiving a comprehensive care program, with that reduction occurring only in patients with an identifiable preceding clinical respiratory tract infection. A similar trend with small numbers of patients was seen for the Navajo and Papago American Indian populations in school-based intervention programs[17,61] and in an Alaskan program.[37] Other school-based interventions[184] have reduced streptococcal prevalence rates but have not gone the necessary further step to show a reduction in rheumatic fever morbidity in a controlled, carefully demarcated population. A recent systematic review and meta-analysis of available evidence supports the premise that a community- or school-based initiative can reduce rheumatic fever by an estimated approximately 60 percent (relative risk 0.41, 95% confidence interval [CI] 0.23, 0.70) acknowledging the eligible studies are of variable quality but are unlikely to be replicated.[135]

An unexplained high incidence of acute rheumatic fever persists in Hawaii, especially in Polynesian and part-Polynesian children.[55,129] Similarly, rates are higher in larger populations of Polynesian (including indigenous Maori) children in New Zealand,[140,168] although increasing evidence from that country points toward low socioeconomic status, including housing and income issues and associated factors such as a lesser degree of education playing a role.[62,115] In some areas of the continental United States, the rate of endemic rheumatic fever continues to exceed that of the general population in some children traditionally considered to be at risk (urban

Trend lines are fitted for each era (1921 through 1945 and 1946 through 1978) separately and take International Classification of Diseases (ICD) revisions into account. The *arrow* separates the two eras. (From Massell BF, Chute CG, Walker AM, Kurland GS. Penicillin and the marked decrease in morbidity and mortality from rheumatic fever in the United States. *N Engl J Med* 1988;**318**:280–6.)

blacks), although not in others (recent Hispanic immigrants).[84] In contrast, in a hospital-based study in another urban area, Hispanic children, reflecting the pediatric population being served, were the most affected.[104]

From the beginning of 1985, the number of patients with acute rheumatic fever in several centers on the U.S. mainland increased. Although these numbers were not large, they represented a definite increase in the outbreak areas (Table 29-2).[232] The resurgence in Utah since 1985 led to more than 600 cases.[157] Nationally, however, the number of diagnoses of acute rheumatic fever, in the absence of robust surveillance data, appeared to continue to decline gradually from 1984 through 1990.[232] The populations (aside from clusters in military populations)[9,247] generally did not seem to be those considered to have been at risk in the past; most patients were white and middle class and lived in suburban or rural communities with ready access to medical care. In the Utah and Tennessee outbreaks,[242,255] the families were larger than the state average. The military outbreaks[9,249] were the first in 2 decades in U.S. military personnel. Factors other than the widespread use of antibiotics and improved availability of health care are likely to be important because group A streptococci are rated moderately infectious agents in close contacts.[72,201] Overcrowded living circumstances long have been considered a risk factor.[183] This hypothesis was not substantiated as an important risk factor by conditional logistic regression in a modern (Yugoslavian) study[245] but was supported in a recent ecologic study, also exploring multivariant relationships where acute rheumatic fever rates are high.[114] The disquieting feature in these more recent U.S. outbreaks was the severity of the illness, especially in the Salt Lake City outbreak: 72 percent of patients had clinical carditis (Table 29-3), 19 percent had severe carditis with or without congestive heart failure, and 3 patients required mitral valve replacement. However, this report was from a cardiology center, which is likely to reflect a referral bias. Earlier U.S. reports documented clinical carditis in initial attacks of rheumatic fever in 40 to 51 percent of patients (1951 through 1965).[152] Longitudinal observations at the same institution suggest a decreasing frequency of clinical carditis (73% from 1921 to 1930, 51% from 1951 to 1960).[36,158]

With the use of Doppler echocardiography, carditis rates in the Utah patients increased to 91 percent (see Table 29-3). The duration of secondary penicillin prophylaxis and endocarditis prophylaxis are important considerations for patients with nonclinical carditis. The place of echocardiography in the diagnosis and management of rheumatic fever continues to evolve (see section on laboratory findings). Rheumatic fever presenting with arthritis may be misdiagnosed or not be admitted to

hospital, which is likely to affect estimates of rates of carditis in studies that are not population-based.[105]

A more recent assessment of hospitalized acute rheumatic fever disease in the United States in children younger than 21 years of age found a low rate of 14.8/100,000 hospitalized children (503 cases).[169] The prevalence of rheumatic heart disease, which represents the result of many years of exposure to the risks for acquiring acute rheumatic fever, seems to have declined in the United States over the course of many years.[174]

Many different racial and ethnic groups have been deemed unusually susceptible to rheumatic fever. They usually have been minority groups within a given area who are of lower socioeconomic status than the general population (e.g., Malays in Singapore, Arabs in Israel, Bantus in South Africa, indigenous Maori and Pacific Polynesians in New Zealand, blacks in the United States, aborigines in Australia).[2,62,107,151] In the United States, when differences in socioeconomic status or degree of crowding were taken into account,[100] the differences in the incidence of rheumatic fever,[99] prevalence of rheumatic heart disease,[174] and mortality from acute rheumatic fever and rheumatic heart disease generally declined or disappeared,[192] at least in the population studied. Rates in blacks were slow to decline, however. Rates became very low in the 1970s, at least in some areas, but cases persisted in other areas.[84,133]

Gordis and associates[98] caution that some other socioeconomically determined factor closely paralleling crowding could be the actual determinant of rheumatic fever. Most authorities agree that the reduction in the incidence and severity of rheumatic fever that has been noted in the United States and Western Europe might be due partly to a higher standard of living and less crowding. In a case-control study in the former Yugoslavia, home dampness, change of place of residence during the previous 5 years, low maternal education, body weight below normal, frequent sore throats, and a positive family history of rheumatic fever were found to be significant risk factors.[245]

A relationship between group A streptococcal throat infection and rheumatic fever was recognized in observations of the latter occurring after outbreaks of scarlet fever.[180] The attack rate noted after group A streptococcal throat infection varied widely (from 3% at Warren Air Force Base[194] to 0.39% in Chicago children).[211] Further observations in the latter study revealed that exudative pharyngitis, a positive throat culture with persistence of group A streptococci beyond 21 days, and the development of significant antibody (antistreptolysin O [ASO]) responses were associated with a higher attack rate that approached 3 percent in the children studied.

Rheumatic fever, similar to streptococcal pharyngeal infection, occurs most commonly in children 5 to 15 years of age. First attacks of rheumatic fever rarely occur in children younger than 3 years of age or in adults older than 40 years because of the relative infrequency of streptococcal infection at these ages and perhaps other factors.

The incidence of acute rheumatic fever is highest in the spring and winter months in temperate zones and coincides with the seasonal variation in streptococcal

pharyngitis. This incidence may be related to the greater tendency for spread of streptococcal infection by closer contact during the colder and damper months,[140,224,245] at least in some climates. In other climates, a seasonal peak for acute rheumatic fever is less pronounced.[34]

PATHOGENESIS

Evidence points toward acute rheumatic fever being preceded by a group A streptococcal upper respiratory tract infection. The events that occur after such infection and that culminate in rheumatic fever are poorly defined, suggesting a complex interaction of numerous factors. With the resurgence of interest in this disease after the outbreaks in the 1980s, laboratory data collected with the use of modern technologies have led to some new insights.[213,214] Pathogenesis involves the host, the environment (see section on epidemiology), and group A streptococci, individually and collectively.

So-called rheumatogenic strains of group A streptococci have been the subject of much discussion, more recently in relation to the latest focal upsurges in rheumatic fever.[30,31,119] Because no factor has been described or isolated, however, such strains remain a hypothesis. To date, rheumatic fever has been shown to occur only after nasopharyngeal infection,[251] although debate and research continue.[65,117] Why the site of infection seems to predispose individuals to the development of rheumatic fever remains an enigma, perhaps related to skin lipids.[118] Acute glomerulonephritis develops after skin or throat infections with a nephritogenic type of group A streptococci (e.g., M-49 and M-12).[251]

Certain streptococcal M protein serotypes are implicated strongly and repetitively in epidemics of acute rheumatic fever. Serotypes M-3, M-5, M-14, M-18, and M-24 have been reported more than once in outbreaks, and M-1, M-6, M-19, M-27, and M-29 have been reported once only.[29] Distinct nucleotide sequences that determine different gene subfamilies encoding the M or M-like protein antigenic domain (*emm* gene) may be the cause of these variations in streptococcal rheumatogenic potential, depending on the site of infection.[28] Other equally prevalent M types rarely, if ever, have been associated with epidemics of the disease[29] or have failed to cause recurrences in susceptible patients.[32] The current resurgence lends limited support for this concept: No predominance of a single serotype within a specific geographic zone was identified in any of the published outbreaks (see Table 29-2). Specific M types and their production of mucoidal colonies, considered to be related to the amount of M protein and virulence,[252] may be more relevant to epidemic than to endemic rheumatic fever.

In Auckland, New Zealand, where rheumatic fever is endemic, in a large urbanized minority population an average of 50 new cases of acute rheumatic fever currently occur annually in children aged 5 to 14 years of age (annual age-specific rate of 25/100,000/yr; Maori and Pacific 60/100,000).[114] Nine years (1984 to 1992) of surveillance of group A streptococcal isolates from hospitalized pediatric patients (one centralized children's facility for 8 of the 9 years in question) yielded 2410 isolates. Only 3 of 38 throat isolates (32 from well-documented cases of rheumatic fever, 6 from siblings) were strains described as possibly rheumatogenic (one each of M-1, M-3, and M-6).[156] None was described as mucoidal.[156] In that series, M types 6, 53, 55, and 66 (and NZ 1437, now known as M-89, when sibling isolates were included as cases) were statistically more likely to be associated with a case of acute rheumatic fever. In the more recent era, isolates associated with acute rheumatic fever and pharyngitis in Hawaii (Table 29-4) are rarely seen in the continental United States.[78] Of importance, the assumed link between rheumatic fever, the disease, and the disease-causing *emm* types is only temporal. It may itself not be sufficient to build a hypothesis for a possible association of initial infection site and acute rheumatic fever.

Strain selectivity is a further consideration. No documented evidence has shown that all members of an M type may be equally able to elicit acute rheumatic fever. Some streptococci from a particular serotype may be associated with acute rheumatic fever and acute poststreptococcal glomerulonephritis, although the two sequelae rarely occur simultaneously.[146,153,156] M types have been shown to be composed of genetically diverse streptococci, not all of which may be established within a community.[155] Genetic analysis of serotype M18 from acute rheumatic fever cases in Utah separated by 12 years showed strains nearly genetically identical.[213] The M type denotes possibly nothing more than a shared type-specific marker, with the property of rheumatogenicity as yet remaining elusive. Streptococcal strains that are opacity

Note: There were 1258 total pharyngitis isolates from Hawaii and 3424 isolates (from the period 1995-2001) included in the Centers for Disease Control and Prevention surveillance data from the United States.

*Isolated from 2 patients.

factor–negative (a lipoprotein lipase) are unlikely to be rheumatogenic, according to some investigators.[119,255] This finding does not hold up in all geographic areas.[156] Surveillance of group A streptococci in multiple geographic zones is ongoing to guide vaccine development.

Although current evidence strongly implicates an immunologic mechanism in the pathophysiology of rheumatic fever, the details of how the disease develops are unclear.[31,64,157,222] Evidence to date strongly suggests an abnormal cell-mediated and humoral immune response to cell membrane streptococcal antigens, which, because of molecular mimicry of human tissues, may result in continued damage to the cardiovascular and nervous systems.[42,105,222] The findings of circulating immune complexes in most patients[63] and the deposition of C3 and immunoglobulin in the myocardium of patients dying of acute rheumatic fever support an abnormal immune response in rheumatic fever.[122]

M proteins from some rheumatogenic group A streptococcal types share antigenic determinants with myosin, with the sarcolemma of cardiac muscle,[68,69] and with antigens of articular cartilage and synovium.[21] The immune response to streptococci may mistake the host antigens as foreign and result in tissue damage. Other streptococcal antigens, such as the group A carbohydrate component, are candidates for mistaken cross-reaction with a glycoprotein in human heart valves.[96] Group A streptococci have components that can amplify or downregulate the immune response.[42] The mechanisms for molecular mimicry leading to central nervous system dysfunction are less defined.[157]

The site of the initial streptococcal infection may be important—lymphatic channels have been shown between the tonsils and the heart.[42] Unusual compartmentalization of rheumatic antigen–positive non-T cells has been shown in patients with acute rheumatic fever, with no positive cells detected in rheumatic tonsils but increased numbers in peripheral blood.[102]

Cell-mediated immunity to streptococcal antigens also is enhanced in patients with rheumatic fever.[222] The lymphocytic infiltrate of heart valves was found to be composed predominantly of $CD4^+$ helper cells.[193] Increased expression of human leukocyte antigen (HLA)-DR on fibroblasts, which can present antigens to $CD4^+$ lymphocytes (cytotoxic/suppressor T cells), has been observed on the heart valves of patients with acute carditis.[76] The cytotoxicity induced in normal human helper and suppressor cells in vitro by purified protein from a type M-5 group A streptococcal organism has been shown to destroy several human cell types, including cultured myocardial cells.[70] T-cell subset study results are conflicting,[172,222] but production of interleukins is reported to be enhanced.[172,173,268] The role of M protein and streptococcal pyrogenic exotoxins as superantigens is being explored and perhaps might explain the exaggeration of the streptococcal immune response.[154,235]

The genetic background of the human host seems to influence susceptibility to rheumatic fever.[41] Aggregation of rheumatic fever cases in families has been recognized for some time.[186] Low concordance for inheritance has been reported in monozygotic twins,[229] although affected siblings have significant concordance for arthritis, residual rheumatic heart disease, and chorea.[215] A recent systematic review and meta-analysis of twin studies estimated heritability across all studies of 60 percent, suggesting whole-genome scanning might provide a clinically useful genetic risk prediction tool for rheumatic fever and rheumatic heart disease.[77] Patarroyo and associates[179] found that the B lymphocytes of patients with rheumatic fever have a specific marker (883 alloantigen) associated with host rheumatic susceptibility.[265,266] It seems to transcend ethnicity,[110,179] although studies in India and Africa were less supportive, and may be similar to an immune response gene.[222,248] This work has been extended with the use of monoclonal antibodies to family members of patients with rheumatic fever.[83,197] Class I HLA molecules have not been associated with acute rheumatic fever. Many studies in different populations have shown an association with HLA-DR, but without a single HLA marker for susceptibility.[222] Genetic factors alone seem highly unlikely to be responsible for susceptibility to rheumatic fever.[153] No predictive marker for susceptibility to rheumatic fever has been defined to date. Studies in different populations have yielded conflicting results exploring the possibility that gene polymorphisms influence severity of heart disease in rheumatic fever patients.[20]

VACCINE DEVELOPMENT

Immunity to group A streptococci and to rheumatic fever is thought to depend largely on antibodies to M protein, a major virulence determinant; such antibodies can opsonize the bacteria in the presence of neutrophils.[132] Immunity is thought to be strain-specific and to depend on antibodies to the variable serotype-specific regions of the protein, and earliest vaccine development followed this pathway.[24] Two early landmark studies showed that vaccines containing purified M protein evoked protective immune response in humans.[25,189] Antibodies against the variable amino-terminal end of the M protein opsonize streptococci in a type-specific manner, but the results of experiments in animals suggest that the conserved carboxyl-terminal end also may be an immune target. Some human evidence suggests that this conserved epitope acts as a subunit vaccine.[190] Complexities in this area include the risk for inducing cross-reacting antibodies that could injure rather than protect.[19,160] Separation of the peptide fragments of M proteins (epitopes) that evoke type-specific and not cross-reacting antibodies was an important step.[39,63] Most of the cross-reactive epitopes identified have been located in the middle of the M proteins (Fig. 29-4) and can be separated from the N-terminal, hypervariable protective epitopes that evoke antibodies with the greatest bactericidal activity.[67]

More than 120 different defined serotypes (M types) of group A streptococci have been identified. In the 1990s, classic M-protein typing was largely replaced by sequence typing of the 5′ end of the M protein *(emm)* gene.[80] Vaccine development[31,35] falls into two broad approaches: vaccines based on common protective antigens of group A streptococci and multivalent vaccines based on type-specific N-terminal regions of the M protein.[67,106,219] A 26-valent vaccine with components

FIGURE 29-4 ■ Erythema marginatum in an 8-year-old girl with acute rheumatic fever.

guided by North American surveillance of acute rheumatic fever, invasive infections, and pharyngitis has been shown to be safe and immunogenic in adults.[166] This vaccine includes 80 to 90 percent of important serotypes in North America. More recent epidemiologic studies with additional data from North America and Europe, as well as some from developing countries, led to a 30-valent vaccine with broader coverage and promising animal model data against vaccine serotypes.[71] In addition, the researchers reported significant levels of bactericidal antibodies against a further 24 of 40 nonvaccine serotypes of group A streptococci.

However, despite 98 percent coverage of pharyngitis isolates in North America, preliminary data from prospective studies of pharyngitis infections in Mali and South Africa indicate only 40 percent and 59 percent coverage.[71] Epidemiologic studies of group A streptococci from low-income countries are sparse.[220] In general, a wider diversity of *emm* types are seen, indicating that vaccine coverage with current tools may be incomplete in other areas, such as in Hawaii,[78] Asia,[191] or New Zealand,[156] where rheumatic fever is endemic in some populations. More comprehensive information for serotype prevalence in such areas of high endemicity is urgently needed.

RHEUMATIC FEVER IN DEVELOPING COUNTRIES

Rheumatic heart disease is considered one of the few preventable chronic diseases.[12] Despite impressive declines in incidence in developed countries (see Figs. 29-1 to 29-3), globally, rheumatic heart disease remains the most common form of acquired heart disease.[128,266] Four fifths of the world's population live in developing countries, where the prevalence of rheumatic heart disease suggests that the incidence of acute rheumatic fever remains at high levels in areas characterized by crowded living quarters and lower socioeconomic conditions. In Soweto, South Africa, the prevalence of rheumatic heart disease in the 1970s was estimated by cardiac auscultation at 7.1/1000 schoolchildren.[165] A recent estimate using echocardiography in two developing country settings

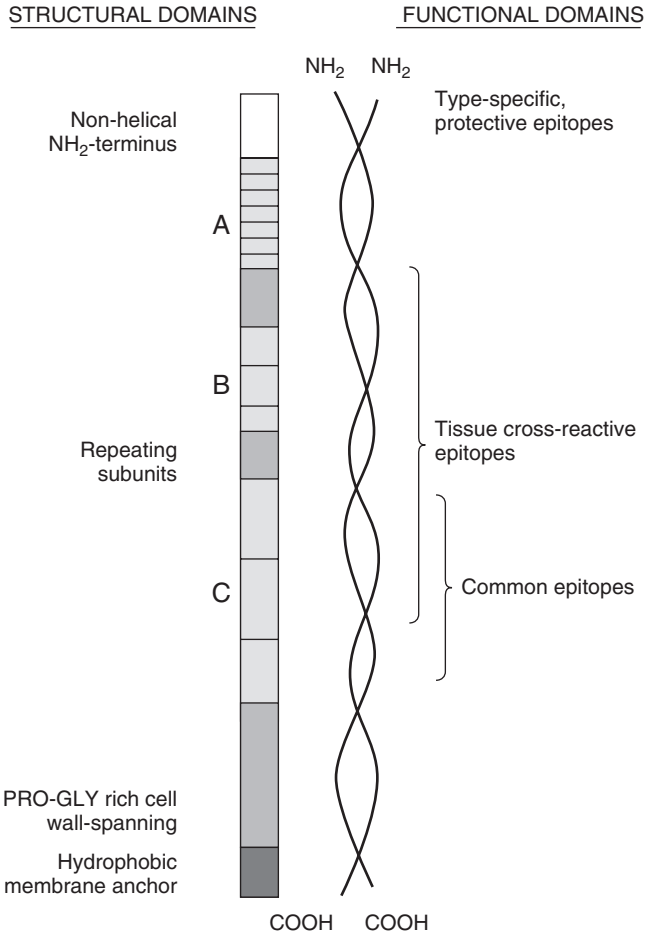

FIGURE 29-5 ■ Schematic representation of the structural and functional domains of streptococcal M protein (From Dale J. Current status of group A streptococcal vaccine development. In: Finn A, Pollard A, editors. *Hot topics in infection and immunity in children IV: Advances in experimental medicine and biology*, vol. 609, New York: Springer; 2008. p. 53–63.)

increased this estimate by nearly 10-fold.[149] Studies have been repeated in other settings (Fig. 29-5) with differing echocardiographic criteria but similar estimates of burden.[148] The true meaning of these findings in asymptomatic subjects in high-prevalence populations requires

a better understanding of the natural history of subclinical carditis, standardization of the echocardiographic criteria, and cost-benefit analyses in various settings. A recent consensus standardization guideline has been published.[199] Reliable, quality-controlled global supplies of benzathine penicillin for prevention of further attacks may need to be considered.[38]

An important recent prospective study in patients 14 years of age or older from Soweto highlights a significant disease burden of new-onset rheumatic heart disease presenting in the third and fourth decades of life,[212] suggesting a presumed unrecognized or subclinical earlier acute rheumatic fever episode most likely in childhood. The contribution of rheumatic heart disease to the burden of hospitalized disease resulting from strokes, atrial fibrillation, and other sequelae requires more elucidation.

Given the difference in medical care delivery, evaluation of the incidence of acute rheumatic fever must be viewed with caution. Estimates suggest, however, an annual incidence of 200 to 400 cases/100,000 population in Soweto.[127] The incidence of rheumatic fever (as judged by hospital admissions for rheumatic heart disease between 1966 and 1980) has remained stable in India during this period of rapid decline in the United States and the West.[2] Some recent publications have attempted to better define the global burden of acute rheumatic fever and rheumatic heart disease (and other group A streptococcal diseases) with variable rigor.[48,206,234] More detail is available from the World Health Organization. Community-based secondary penicillin prophylaxis programs in developing countries are considered cost-effective and more achievable than is primary prevention.[127]

PATHOLOGY

The unique pathologic lesion of rheumatic fever is the Aschoff body, which generally is considered to be a granuloma that results from injury to collagen fibers. Classically, Aschoff bodies are found in the heart, usually in the left atrial appendage, but similar foci can be found in the synovia of the joints and in and around joint capsules, tendons, and fascia.[202]

The early pathologic response to rheumatic fever may be an exudative reaction with Aschoff-like bodies as an inflammatory focus. They are cardiac or extracardiac, with a central area of fibrinoid necrosis surrounded mostly by polymorphonuclear leukocytes. Clinically, this condition may be manifested as arthritis and spontaneously subside in 2 to 4 weeks. No residual joint damage results. The proliferative phase of classic Aschoff nodules, which consists of central necrosis surrounded by a rosette of large mononuclear cells, giant multinuclear cells, and other cell types, is confined to the heart and usually causes pancarditis with simultaneous involvement of all three layers (i.e., the pericardium, the myocardium, and the endocardium). This event may result in permanent valvular damage in the following order of frequency: the mitral valve, the aortic valve, the tricuspid valve, and, rarely, the pulmonary valve.

The heart disease encountered clinically usually is mitral regurgitation, aortic regurgitation, or both. The scarring that leads to valvular stenosis (mitral or aortic) typically takes decades to develop but may occur much faster in hyperendemic areas. This process is not the full story, however, because although rheumatic mitral valve stenosis occurs more commonly in India[205] and occasionally in other less advantaged populations, it was never a common occurrence in the United States or the United Kingdom at the height of rheumatic fever incidence.[231]

The presence of Aschoff bodies is not evidence of rheumatic activity because these lesions are found in biopsy specimens of the left atrial appendage many years after an acute attack of rheumatic fever. Little is known about the pathology of Sydenham chorea, and the pathologic changes cannot be related to the clinical manifestations. Patients rarely die of this form of rheumatic fever.

CLINICAL COURSE

The stage is set for the development of rheumatic fever in a susceptible host after a pharyngeal infection by one of the types of group A β-hemolytic streptococci.[152,216] Not all serotypes (M or *emm* types) appear to be equally rheumatogenic (see earlier section on pathogenesis). Rheumatic fever develops in approximately 1 to 3 percent of children with known epidemic untreated exudative pharyngitis and a culture positive for group A streptococci. The frequency decreases to less than 1 percent, as shown in the one controlled study involving children,[211] when patients with less severe or less precisely diagnosed streptococcal infections are included. This finding has been replicated more recently in a large community- and school-based randomized, control trial with high consent and retention rates in New Zealand in an area with endemic rheumatic fever. The attack rate observed was approximately 0.2 percent.[140]

The preceding pharyngitis is not recognized as an illness by the patient or parents in approximately 10 to 33 percent of cases of acute rheumatic fever, although 50 to 60 percent of patients remember having a sore throat.[97] In the New Zealand trial, episodes of sore throat (with appropriately increased streptococcal serology) in this carefully monitored series preceded development of acute rheumatic fever in 14 of 19 (74%) of the cases enrolled in the program at the time of presentation.[141] In some case series, this figure is lower but the methodology is less vigorous (see Table 29-2). The infection is followed by a latent period that averages 19 days in duration,[194] during which time the patient seems well. The range seems to be between 1 and 5 weeks but has been difficult to establish.[50] In the New Zealand trial, the average latent period was 27 days (range, 2 to 49 days) for seven rheumatic cases with proven group A streptococcal pharyngitis and raised streptococcal titers.[141] The average latent period is the same for recurrent attacks as for initial episodes.[50]

Acute rheumatic fever then begins. Table 29-3 suggests a clinical profile in the United States, although

recurrent cases with their increased risk for carditis are included. In a prospective study in India, 67 percent of initial episodes were associated with migrating arthritis involving one or more of the large joints[204] accompanied by a fever of 38° to 39° C (100.4° to 102.2°F), malaise, and anorexia. Just as the redness, swelling, and pain in a knee subside, the whole process may start again in the ankle. The elbows and wrists are likely to be involved. Arthritis of the hip also occurs.[162] The joint involved may be exquisitely tender, with the patient exhibiting extreme reluctance to move the joint or mobilize. Typically, multiple joints are involved in tandem, with overlap over the course of time, when symptoms are not suppressed by anti-inflammatory therapy. The whole polyarthritic episode usually subsides over 4 weeks, with no residua remaining. The joint inflammation may be of low grade in some individuals, without limitation of motion or outward manifestations of redness and swelling (arthralgia). The literature supporting monoarthritis that does not develop into migrating polyarthritis in acute rheumatic fever is unconvincing.* The clinician should act cautiously, however, in an area endemic for rheumatic fever in the early phase of presentation. The development of polyarthritis in a patient with a culture-negative monoarthritis (e.g., a hip joint in a patient without prior antibiotic exposure) may be aborted by nonsteroidal anti-inflammatory drugs (NSAIDs).[258] An early echocardiogram may assist in establishing the diagnosis (see section on laboratory findings).[3]

Carditis generally appears early in the illness (first 2 to 3 weeks) if it is going to occur.[1] It may be silent in the absence of elevated fever or symptoms of pericarditis or cardiac failure. The clinical signs are the development of a new heart murmur, cardiac enlargement, congestive cardiac failure, a pericardial friction rub, or signs of cardiac effusion.

However, the mode of onset of acute rheumatic fever can be quite variable, and access to medical care, the health knowledge of the patient or family, or the awareness of health care personnel may be factors determining when in the illness the patient initially seeks medical care. Indolent carditis, as an insidious or even subclinical presentation now recognized by the Jones criteria (Table 29-5), may present without other manifestations to fulfill the Jones criteria as the initial episode is sometime in the past. This was a recognized presentation in the New Zealand school trial.[141]

In a classic presentation on examination, the striking findings are the patient's pallor and discomfort, especially on movement of the affected joints. Carditis usually appears within 3 weeks of the start of the illness, and in the absence of high fever or symptoms of acute pericarditis or congestive heart failure, it may be symptomatic.[1] Examination of the heart may reveal in at least half of patients a grade 2/4 apical pansystolic murmur that is transmitted to the axilla (mitral insufficiency) with or without an apical mid-diastolic flow murmur (Carey-Coombs murmur); half of these patients also may experience an early diastolic grade 2/4 murmur at the left sternal edge (aortic insufficiency). The latter can also occur alone. The tricuspid valve is not usually involved and the pulmonary valve very rarely. In addition, less commonly, the child can have congestive heart failure or cardiac enlargement, indicative of active carditis. Carditis is more likely to occur in younger children. Pericarditis may be suspected with muffled heart sounds, a frictional rub, or chest pain. It becomes less common as acute rheumatic fever in a population becomes less severe. Ruptured chordae tendineae in a patient with fulminant carditis may present as unilateral pulmonary edema.[8] Death is a rare but well-described sequela of the acute phase of the disease. Murmurs of mitral and aortic stenosis are associated with chronic but not with acute rheumatic valve disease.

Echocardiography in acute rheumatic fever cases with congestive cardiac failure has shown preserved left ventricular systolic function and/or severe mitral or aortic regurgitation.[79,91,239] Serum levels of cardiac troponin I are not elevated in acute rheumatic fever patients with heart failure.[257]

The distinctive rash, erythema marginatum, was observed in up to 12 percent of patients in these case series (Fig. 29-6; see Table 29-3). It is neither pruritic nor

painful. The pink, slightly raised macules, usually seen initially on the trunk and proximal ends of the extremities and never on the face, fuse centrally and coalesce to form a serpiginous pattern. The lesions may disappear after a few hours or may reappear intermittently over the course of weeks, especially after a warm shower or bath.

Subcutaneous nodules, usually associated with severe carditis, also occur uncommonly (<10% of patients). They are firm and painless and are found over bony surfaces or prominences and over tendons. Acute rheumatic fever is not likely to be diagnosed on the basis of the latter two major criteria without another major criterion.

Sydenham chorea, or St. Vitus dance, may be the only manifestation of rheumatic fever, or it may be associated with other disease manifestations. All laboratory parameters, including streptococcal serology, may be normal. It becomes less common as acute rheumatic fever becomes less severe in a population, presumably as a result of improved awareness and earlier presentation of other manifestations of acute rheumatic fever. Chorea is characterized by purposeless (most often bilateral, uncoordinated, involuntary) movements, mostly of the hands, feet, and face, that develop over the course of weeks and are accentuated by excitement and emotional stress. They disappear during sleep. Sensation remains intact. The speech can be explosive and indistinct, and the handwriting can be clumsy. Handwriting is a useful objective means of monitoring the course of the disease. The child has difficulty counting rapidly and holding the protruded tongue still. The fingers and wrists are hyperextended when the fingers are outstretched, and the palms usually are turned outward when the arms are held above the head. Handgrip generally is weak and may consist of spasmodic contractions followed by rapid relaxation (so-called milkmaid grip). The patient may be easily irritated and quarrelsome. Chorea typically is a delayed manifestation of rheumatic fever and may develop after other signs of the disease have subsided, commonly appearing 2 to 6 months after the streptococcal infection. Historically, observers think residual heart disease occurs less commonly when chorea is the only manifestation of rheumatic fever, but in the echocardiographic era this hypothesis may prove not to be the case.[3] The importance of prophylaxis in those with chorea to prevent recurrent attacks and possible subsequent carditis was reaffirmed in Kuwait.[145] Permanent serious residual neurologic deficits have not been observed. A 25-year review found the duration of chorea to be 1 to 22 weeks, with a median of 12 weeks.[176] Rare cases may last 2 to 3 years.[4,15,44] Recurrent attacks are common and may occur despite faithful adherence to prophylaxis with intramuscular benzathine penicillin.[27,233] The neuropsychiatric sequelae of chorea were reviewed recently.[170]

Some cases of chorea are mild or atypical and may be confused with motor tics or the involuntary jerks of Tourette syndrome. Confusion may ensue between Sydenham chorea and these conditions. The term *pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS)* refers to a subgroup of children with tic or obsessive-compulsive disorder whose symptoms may develop or worsen after an episode of group A streptococcal infection. The following five criteria have been used to define the PANDAS subgroup[130,227]:

1. The presence of a tic disorder, obsessive-compulsive disorder, or both
2. Prepubertal age of onset (usually between 3 and 12 years of age)
3. Abrupt onset of symptoms, episodic course of symptom severity, or both
4. Temporal association between exacerbations of symptoms and streptococcal infection (approximately 7 to 14 days)
5. Presence of neurologic abnormalities during periods of exacerbation of symptoms (typically adventitious movements or motoric hyperactivity)

The evidence supporting PANDAS as a distinct disease entity has been questioned.[130] In any population with a high prevalence of acute rheumatic fever, clinicians should rarely (if ever) make a diagnosis of PANDAS and rather should err on the side of overdiagnosis of acute rheumatic fever and secondary prophylaxis. If acute rheumatic fever is excluded, secondary prophylaxis is not needed, but these patients should be followed carefully to ensure they do not develop carditis in the long term (see Chapter 82).

The average duration of an attack of acute rheumatic fever is approximately 3 months when unaltered by anti-inflammatory therapy.[152] Fewer than 5 percent of cases persist longer than 6 months with active symptoms, so-called chronic rheumatic fever.[229]

LABORATORY FINDINGS

The degree of inflammation in patients with acute rheumatic fever is measured by nonspecific indicators, such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).[152,216] Unless the patient has taken corticosteroids or salicylates, these test results almost always are

positive in patients with polyarthritis or acute carditis but are normal in patients with chorea. The magnitude of the ESR is proportional to the intensity of the inflammatory reaction but is not site-specific (i.e., it can be high with polyarthritis or carditis). The ESR is typically more than 80 mm/hr in acute rheumatic fever.[142] The ESR may be decreased in congestive heart failure, whereas the CRP may be elevated in congestive heart failure attributable to any cause. The ESR may remain elevated for 6 weeks to 3 months in an untreated attack of acute rheumatic fever. Anti-inflammatory agents may reduce the ESR, but it rebounds if the drugs are stopped before the rheumatic process has run its course. Although chronic elevation of the ESR (>6 months) is not understood, it is not sufficient reason on its own to limit a patient's activities.[230] The CRP may reflect the patient's rheumatic activity more precisely than may the ESR.[152]

Chest radiographs are useful for detecting cardiomegaly, which may be caused by dilation, preexisting heart disease, or pericardial effusion. The degree of enlargement is helpful in judging severity. The electrocardiogram may show a prolonged atrioventricular conduction time, usually evidenced by a prolonged PR interval or even greater degrees of heart block.[196] Generally, an increase in the PR interval in tracings with comparable rates is considered significant.[152] Upper limits of normal by age are available.[142] Atrioventricular conduction abnormalities per se bear no relation to the ultimate prognosis of patients. Changes of myocarditis and pericarditis also are seen.

Every patient with suspected rheumatic fever should be considered for an echocardiogram. The roles of two-dimensional and Doppler echocardiography in establishing the diagnosis and determining the prognosis of acute rheumatic fever are becoming clearer.* In a prospective blinded study using febrile controls and strict color and pulsed Doppler criteria, pathologic left-sided heart regurgitation could be differentiated from physiologic regurgitation.[1] Several centers using similar strict echocardiographic guidelines have observed subclinical carditis in acute rheumatic fever.[87,88,241,242] The status of echocardiographic evidence as a major or minor Jones criterion remains to be settled by the American Heart Association.[85] It has important implications for patients with polyarthritis or chorea as a sole major criterion[3,216] or patients without major criteria and only echocardiographic evidence of mitral or aortic regurgitation. In an area of high endemicity (New Zealand), strict criteria have evolved and are incorporated into common usage.[16,142]

However, in a prospective randomized trial of prevention of acute rheumatic fever (see earlier discussion), only three additional cases (3 of 59 [5%]) met the case definition for acute rheumatic fever using the New Zealand Rheumatic Fever diagnostic criteria, which allows echocardiographic carditis to be a major or minor criterion in the presence of other major or minor criteria and evidence of preceding streptococcal infection.[141] Every case was scrutinized by an independent group of clinicians, including a cardiologist.[141] Australia also has incorporated echocardiographic criteria into guidelines.[47] Publications included in a systematic review found a prevalence of 17 percent of subclinical carditis in acute rheumatic fever.[237] However, no comment was made in this paper on the use of echocardiographic-only carditis as a stand-alone criterion, beyond the current Jones criteria.[216] Careful studies on the long-term prognostic significance of subclinical carditis need to be performed.[43]

In 2012, an international consortium published guidelines on minimal criteria for a diagnosis of rheumatic heart disease with echocardiography.[199] These criteria do not address the differentiation between acute carditis and chronic rheumatic heart disease. The criteria for pathologic regurgitation are unlikely to be different and have been incorporated into other guidelines.[16,47,142] Morphologic changes may be different in acute rheumatic fever and require clarification. Assessment of left ventricular size and function are an important part of the evaluation of a patient with rheumatic fever, especially if surgery is being considered.[91]

A positive throat culture for group A β-hemolytic streptococci as evidence of a recent streptococcal infection seldom is found in an acute rheumatic fever case, although 50 percent of such patients could be carriers of the organism.[123] In the New Zealand randomized trial, of patients with rheumatic fever who reported sore throat episodes (n = 14), 57 percent (8 of 14) had a positive throat culture and appropriately increased serology.[141] A positive culture may be helpful if it can be related to the time of the acute infection.

Corroboration of a previous streptococcal infection is better determined serologically. Many streptococcal antibody tests are available.[207,256] Antibody titers may be elevated in the absence of clinical or bacteriologic evidence of streptococcal pharyngitis (5 of 19 acute rheumatic fever cases in the New Zealand program).[141] The ASO titer is the most popular antibody test. It measures the inhibition of rabbit red blood cells by specific antibody to streptolysin O, an extracellular product of β-hemolytic streptococci that in its reduced form hemolyzes red blood cells. The "normal" level for an ASO titer usually is defined as the highest titer exceeded by only 20 percent of a population, but it is influenced significantly by age, geography, season, and other factors.[120,207] ASO titers of 500 Todd units or greater are rare findings in normal schoolchildren and are good evidence of a recent streptococcal infection. ASO titers less than 250 Todd units could be considered normal; titers of 250 to 320 Todd units should be considered borderline elevated. Approximately 50 percent of patients with acute rheumatic fever have ASO titers in this range, and approximately 60 percent have titers of 500 Todd units or greater.[216] Conversely, ASO titers can be normal in 20 percent of patients with acute rheumatic fever.[223]

A recent streptococcal infection is more likely to be shown if more than one antibody titer is measured (e.g., antistreptokinase and antihyaluronidase).[223] Anti–deoxyribonuclease B is currently the most favored test because of its better reproducibility.

The Jones criteria (see Table 29-5) call for an elevated or increasing titer of an antistreptococcal antibody.[216] The onset of clinical acute rheumatic fever usually

*References 1, 85, 86, 142, 216, 240, 241, 242, 244, 260.

coincides with the peak of the streptococcal antibody response. It may stay elevated for many weeks. The absence of an elevated antistreptococcal titer, if three different antibodies are measured, means, however, that the clinician can be 95 percent certain that the patient has not had a streptococcal infection within the recent past. In patients with pure chorea or indolent carditis, antibody levels may have declined to normal because of the length of the latent period between the development of streptococcal infection and the manifestation of this symptom. A slide agglutination test is available, but cannot be recommended at this time because of inconsistencies in results caused by variations in different lots of test material.[263]

The synovial fluid in joints affected by acute rheumatic fever contains 10,000 to 100,000 white blood cells/mm^3, which are mostly neutrophils. The protein concentration is approximately 4 g/dL, glucose levels are normal, and a good mucin clot is present.[112] A more recent report corroborates the cellular findings and highlights similarities with septic arthritis.[109]

DIAGNOSIS

An accurate diagnosis of acute rheumatic fever is vital because a misdiagnosis may lead to future serious cardiac disease but overdiagnosis will commit the patient to a long-term unpleasant therapy—benzathine penicillin every 4 weeks.

The signs and symptoms of rheumatic fever vary greatly, depending on the stage of the disease, the epidemiology of the rheumatic fever in that place at that time, the severity of the disease, and the sites of involvement. In the absence of a diagnostic test or pathognomonic sign, Jones suggested a series of criteria (major and minor) (see Table 29-5) that have stood the test of time, with ongoing modifications.[85,150] These are an estimate of probability of the likelihood of acute rheumatic fever. The keystone on which the Jones criteria[216] rest is the demonstration of a recent streptococcal infection. Because few patients with acute rheumatic fever have positive throat cultures, demonstration of a previous streptococcal infection by a rising titer of one or more of the extracellular streptococcal antibodies is crucial confirmatory evidence to establish a recent streptococcal infection. However, in the absence of the appropriate constellation of signs and symptoms for acute rheumatic fever, the mere presence of an elevated titer to one or more of the streptococcal antibodies (see the section on laboratory findings) means only that the subject has had a recent group A β-hemolytic streptococcal infection, site unspecified.

Clinical manifestations in outbreaks in the 1980s are summarized in Table 29-3. Before this time, during the period of declining incidence in the United States, carditis was found in fewer than half of rheumatic patients and generally was less severe.[158] Joint involvement alone was the most common manifestation, so arriving at diagnostic certainty was difficult. A common avoidable error is the premature administration of NSAIDs or corticosteroids before the signs and symptoms become distinct; such therapy leaves in doubt the necessity of administering secondary prophylaxis without a firm diagnosis.[258]

In contrast to the revised Jones criteria (1965), more updated criteria (1992)[216] are designed to establish a diagnosis of the initial attack of acute rheumatic fever; a previous attack of rheumatic fever or rheumatic heart disease no longer is a minor manifestation. Echocardiography currently is not a stand-alone criterion for the diagnosis of acute rheumatic fever in the United States using these criteria (see the section on laboratory findings); however, chorea and indolent carditis are considered stand-alone criteria for establishing the diagnosis of rheumatic fever. Recurrences of rheumatic fever in patients with a reliable history of rheumatic fever or clear-cut rheumatic heart disease can be diagnosed by the demonstration of a single major or several minor criteria if supporting evidence of a recent group A streptococcal infection is present.

So-called poststreptococcal arthritis has been discussed as a possible entity when the initial symptoms and signs are atypical for acute rheumatic fever, fail to respond to salicylate therapy, or both. In some cases, rheumatic heart disease has ensued.[74] In all such patients who fulfill the Jones criteria, a diagnosis of rheumatic fever should be considered, particularly for the purpose of administering secondary penicillin prophylaxis.[19]

Criteria have been proposed for establishing the diagnosis of poststreptococcal reactive arthritis that have yet to stand the test of time.[18] The variable response to salicylates in published series of this proposed disease entity has not often been well documented with serum salicylate levels.[95] A shorter latent period is proposed, but the latent period between a group A streptococcal throat infection in original investigations of rheumatic fever varied (mean, 18.6 days), with 10 percent developing disease within 8 days (see the section on clinical course).[138,194] If this diagnosis is considered and rheumatic fever per se is not supported, vigilant follow-up for cardiac sequelae should ensue and penicillin prophylaxis should be reconsidered.[93] This diagnosis should be considered with caution in areas endemic for rheumatic fever.

A prospective epidemiologic study with rigorous application of an agreed case definition is needed to clarify this proposed disease entity.

An atypical presentation of chorea (e.g., hemichorea) warrants consideration of neuroimaging.[269]

DIFFERENTIAL DIAGNOSIS

Rheumatic fever can present in diverse ways (acute polyarthritis, congestive heart failure, chorea, or a combination of these), and no specific diagnostic test for the disease exists; thus, the differential diagnoses in an individual patient may be extensive. Many other diseases might be confused with acute rheumatic fever.[134] In polyarthritis without clinical or echocardiographic evidence of carditis and fulfilling the Jones criteria, rheumatic fever is a diagnosis of exclusion. A search for alternative diagnoses is recommended,[142] including rheumatoid arthritis, suppurative bacterial arthritis (including gonococcal arthritis in adolescents), reactive arthritis (e.g.,

after *Yersinia*[131] or *Mycoplasma*[171] infection), infective endocarditis, sickle-cell anemia, leukemia, Lyme disease,[188] rubella, and poststreptococcal reactive arthritis (see earlier discussion). Before presentation to medical care, the first swollen joint may be attributed to injury. A follow-up echocardiogram after 2 to 3 weeks may reveal late-presenting carditis.[1,246]

With the help of the Jones criteria and time, alternative diagnoses usually can be excluded. Heart involvement with rheumatoid arthritis is a rare occurrence. In suppurative arthritis, showing the infecting bacteria by smear and recovery by culture provide the answer. However in an area endemic for rheumatic fever, aseptic monoarthritis without previous antibiotic exposure should be considered rheumatic fever until proved otherwise.[162] Treatment for possible septic arthritis may need to ensue while the diagnosis evolves. In the absence of an audible cardiac murmur, echocardiography revealing subclinical mitral or aortic valve regurgitation may be very helpful. With sickle-cell disease, the bone is affected and not the joint, and a sickle-cell preparation helps establish the diagnosis. A blood smear usually establishes the diagnosis of leukemia.

The diagnosis of isolated Sydenham chorea based on presenting symptoms may be reinforced by an abnormal echocardiogram in the absence of clinical carditis. Other, much rarer considerations, especially in an area not endemic for rheumatic fever, include systemic lupus erythematosus, Wilson disease, juvenile Huntington chorea, and various medications.[49,134]

Common errors include diagnosing acute rheumatic fever and prescribing NSAIDs when a single joint is involved (see the section on clinical course)[258]; when an innocent murmur is present; when a nonspecific rash, especially an urticarial or erythema multiforme rash, erroneously is identified as erythema marginatum; and when other symptoms similar to chorea (e.g., tics, phenothiazine-induced extrapyramidal syndrome) are misinterpreted.[116] Committing a child to many years of penicillin prophylaxis requires careful decision making at the time of establishing the diagnosis.

TREATMENT

Therapy for acute rheumatic fever is symptomatic to control the inflammation, decrease the fever, and keep cardiac failure in check.[50,66,134,165,228] Neither salicylates nor corticosteroids are thought to affect severity or outcome.[12] Cardiac drugs (e.g., diuretics, angiotensin-converting enzyme inhibitors, β blockers) may improve impaired function. The long-term benefits have not been studied systematically. If the physician thinks a patient has acute rheumatic fever, a trial of salicylates may be useful as symptomatic therapy. If the diagnosis is uncertain, however, pain relief such as acetaminophen should be used as an interim measure to allow migrating polyarthritis to occur. This approach has not been evaluated critically.

The most experience and published evidence for management of the arthritis of acute rheumatic fever is with salicylates. Characteristically, the joint inflammation and fever subside in 24 to 48 hours with salicylate treatment if the serum level is 10 to 20 mg/dL, which usually is achieved by a dose of 60 to 100 mg/kg/24 hr (not exceeding 6 g/day in divided doses). This dose may be increased, but the clinician is advised to measure serum salicylate levels and adjust the dose regimen accordingly. A higher dose may result in the undesirable development of salicylism (tinnitus and hyperpnea). Except for occasional patients with rheumatoid arthritis, no other forms of arthritis respond in this dramatic way to aspirin. Salicylate therapy is recommended for 1 to 2 weeks and then can be reduced gradually, keeping in mind that inflammatory markers suggesting ongoing disease activity may persist 3 months or longer. Joint symptoms may recur, obviating a more gradual withdrawal of aspirin.

Most acute rheumatic fever episodes subside within 6 weeks, and 90 percent resolve within 12 weeks. Approximately 5 percent of cases require 6 months or more of salicylate therapy.[224] If lengthy therapy is required, influenza and varicella vaccines are important considerations to reduce the potential for developing Reye syndrome.[59] Newer NSAIDs for the treatment of acute rheumatic fever have been studied in limited fashion.[111,238] Naproxen 10 to 20 mg/kg/day given in two divided doses (maximum dose 1250 mg) had a dramatic effect similar to that of aspirin and is well-tolerated. Advantages are twice-daily administration, the availability of elixir, less hepatotoxicity, and no need to determine serum levels. No data have been published on the use of ibuprofen in rheumatic fever. Breakthrough symptoms of acute arthritis in patients on ibuprofen have been observed and subsequently controlled by naproxen (personal observation).

No evidence has substantiated that steroid therapy is superior or that treatment with steroid or aspirin decreases the severity or prevents the development of residual heart disease.[6,12,56] Both treatments are palliative and not curative. They are, however, effective anti-inflammatory agents for controlling the acute exudative manifestations of rheumatic fever. Steroids are more likely to reduce acute symptoms promptly and may be indicated for severely ill patients in whom inflammatory edema of the myocardium may be life-threatening during the acute stage of the illness.[13,142] The effect of more modern NSAIDs has not been evaluated in this way.

A randomized controlled trial of intravenous immunoglobulin, a proven immunomodulator, in acute rheumatic fever (excluding chorea) failed to alter the natural history. No detectable difference was noted in the clinical, laboratory, or echocardiographic parameters found during the subsequent 12 months.[246]

Bed rest has not been studied critically.[152] Restriction of physical activity until the rheumatic process has become quiescent is a time-honored method of treatment. It has been based on the assumption that the workload of the inflamed heart is related to the degree of residual scarring. Suggested guidelines include 6 weeks of bed rest, depending on whether carditis is present, followed by gradual ambulation indoors over the course of a further 6 weeks before outside activity, in modified fashion, occurs.[16] Patients with severe carditis who have congestive heart failure are managed more conservatively.

All patients at diagnosis should receive penicillin, even if the throat culture does not reveal group A β-hemolytic streptococci. Patients then can be placed on the secondary preventive treatment regimen, which may be either oral penicillin V 250 mg twice per day, or injections of benzathine penicillin 1.2 million U every 4 weeks. The parenteral route has been shown to be more effective in the New Zealand setting[89,177] (Figure 29-7) and by others (Table 29-6).[262] In high-risk situations (e.g., after a recurrence in a compliant patient), administration of benzathine penicillin every 3 weeks has been advised (see the section on prevention for more detail).[60]

Rarely, a patient has congestive heart failure.[142] A diuretic, fluid restrictions, or both are recommended for mild to moderate failure. Angiotensin-converting enzyme inhibitors should be considered for more severe failure, particularly if aortic regurgitation is present. Experience with β blockers in acute rheumatic carditis is very limited, and their use is not recommended.

Chorea is benign and self-limited. Mild or moderate chorea does not require any specific treatment aside from rest and a calm environment, perhaps in the hospital. Overstimulation or stress can exacerbate the symptoms. The potential toxicity of recommended medication for severe distressing or limiting chorea should be taken into consideration. Aspirin does not have a significant treatment effect.[152] A randomized trial of prednisone in Sydenham chorea showed efficacy.[181] More studies are awaited to confirm this finding.

Small studies of intravenous immunoglobulin have suggested more rapid recovery from chorea,[226] but they have not shown reduced incidence of long-term valve disease in acute rheumatic fever without chorea.[246] Until more evidence is available, intravenous immunoglobulin is not recommended except for severe chorea refractory to other treatments.

Carbamazepine and valproic acid now are preferred to haloperidol, which previously was considered the first-line medical treatment for chorea.[73,90] A small prospective comparison of these three agents concluded that valproic acid was the most effective.[182]

Other antichorea medications should be avoided because of potential toxicity. Because of the small potential for liver toxicity with valproic acid, the recommendation is that carbamazepine be used initially for severe chorea requiring treatment and that valproic acid be considered for refractory cases. A response may not be seen for 1 to 2 weeks, and successful medication may reduce, but not eliminate, the symptoms. Medication should be continued for 2 to 4 weeks after chorea has subsided and then withdrawn gradually. Recurrences of chorea usually are mild and can be managed conservatively, but in severe recurrences, the medication can be restarted if necessary.

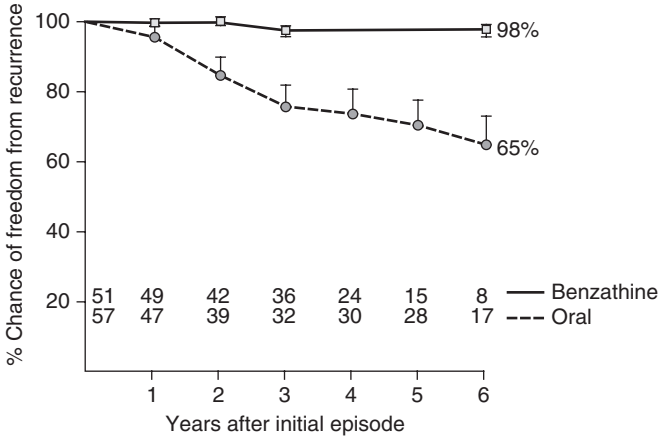

FIGURE 29-7 ■ Actuarial curves showing chance of freedom from recurrence of rheumatic fever after a first attack depending on type of penicillin prophylaxis initially instituted 1968-1982. The bars on the curves refer to the standard error. The figures under the curves refer to the number of patients at risk at each time interval. (From Frankish JD. Rheumatic fever prophylaxis: Gisborne experience. *N Z Med J* 1984;**97**:674–5.)

CARDIAC SURGERY

Aggressive surgical therapy, with increasing acceptance that mitral repair rather than replacement is the treatment of choice for mitral regurgitation,[14,250] may be indicated in patients with severe active rheumatic heart disease. A meta-analysis provides strong support for repair relative to replacement surgery in adult patients.[208] Repair was associated with higher repeat operation in the presence of a risk for disease progression. Data specific to children with rheumatic heart disease (mean age 12.7 years) for long-term outcomes of mitral valve repair have recently become available, demonstrating superiority to replacement.[198] Repair offers a survival advantage and a greater freedom from valve-related morbidity (e.g., a thrombotic, embolic, or hemorrhagic event), without compromised long-term durability. In the

Rheumatic fever in children and adolescents: a long-term epidemiologic study of subsequent prophylaxis, streptococcal infections, and clinical sequelae. III. Comparative effectiveness of three prophylaxis regimens in preventing streptococcal infections and rheumatic recurrences. *Ann Intern Med* 1964;**60**(suppl 5):31–45.

short term, repair was associated with a higher early repeat operation rate but freedom from repeat operation over the 11-year mean follow-up period was equal to replacement.

Extensive published experience in South Africa[22,53] and France[53] has challenged the concept that congestive heart failure and death during active carditis are caused exclusively by myocarditis, rather than incompetence of the valve. Studies on left ventricular mechanics support this with new evidence.[91] In addition, primary myocardial involvement as evidenced by histologic abnormalities of the myocardium has been well documented during acute rheumatic fever.[175,228] Careful postoperative management, including at least 4 months of physical rest, diuretics, and vasodilation with angiotensin-converting enzyme inhibitors, is thought to improve the long-term outcome by avoiding increased blood pressure and myocardial contractility before the repair has consolidated.

Surgery is ideally deferred until active inflammation as best judged by CRP measurements has subsided. Rarely, valve leaflet or chordae tendineae rupture leads to severe regurgitation; this event requires emergency surgery, which can be performed safely by experienced surgeons, although the risk seems to be slightly higher than when surgery is performed after active inflammation has resolved.[5,8]

PROGNOSIS

Carditis is the most serious manifestation of acute rheumatic fever and is the only aspect that has well-defined permanent sequelae.[250] Up to approximately 80 percent of patients have cardiac involvement during their acute episode, with 20 percent with moderate or severe rheumatic heart disease in modern series using echocardiography.[141,242] The rate of progression of valvular regurgitation resulting from rheumatic carditis is subject to wide individual variation; however, many cases tend to progress over the next 5 to 10 years, particularly if acute rheumatic fever recurs.[167] Moderate to severe valve lesions during the initial attack of acute rheumatic fever is a strong predictor of rheumatic heart disease in the long term.[46,58,167] Valve lesions of a mild nature are likely to resolve over time in the absence of recurrences of acute rheumatic fever.[246] According to a study conducted in Brazil by Meira and colleagues,[167] 69.5 percent of patients with moderate or severe carditis (in the initial attack of acute rheumatic fever) had clinical evidence of rheumatic heart disease, and all of the patients with severe carditis had persistent rheumatic heart disease, at a mean follow-up of 5.4 years.

Before the availability of penicillin, the prognosis for patients with acute rheumatic fever was even more stark. In a 20-year follow-up study by Bland and Duckett Jones,[36] a patient with marked cardiomegaly, congestive heart failure, or pericarditis had about a 70 to 80 percent chance of dying in the 10 years before the advent of secondary prevention programs, open heart surgery, and use of prosthetic valves. The prognosis today is not as poor, although the recurrence rates (with the attendant increased risk for carditis in individual patients) reported after some outbreaks[241,267] suggest a careful look at secondary prevention and its delivery. The risk for rheumatic heart disease at 1-year[12] and 10-year[58] follow-up is 70 percent for patients with cardiomegaly or heart failure and who survive. Most of these patients have mitral insufficiency, and approximately 50 percent also have aortic insufficiency.

Of patients with no or questionable carditis[12] during their attack of rheumatic fever, only 6 percent were found to have heart murmurs when re-examined 10 years later. Heart disease was present at follow-up in 30 percent of the patients initially found to have only apical systolic murmurs and in 40 percent of patients with basal diastolic murmurs during the acute phase. Patients with chorea may have a slightly lower incidence of residual heart disease.[144] Robust data on prognosis from the echocardiographic era are required.

PREVENTION

Most (approximately two thirds) but not all episodes of rheumatic fever have a streptococcal throat infection that comes to medical attention. Denny and associates[75] and Wannamaker and colleagues[254] made one of the most important research contributions in the last 50 years when they showed that rheumatic fever can be prevented in most susceptible subjects if the preceding pharyngeal infection by one of the group A β-hemolytic streptococci is treated adequately. These studies used intramuscular depot procaine penicillin G in oil, now replaced by benzathine penicillin. The effectiveness of other antimicrobial agents (benzathine penicillin, chlortetracycline, sulfadiazine, oxytetracycline) in the prevention of rheumatic fever also was studied. Eradication of the streptococcus was shown to be essential in the prevention of rheumatic fever.[50] A 10-day course of oral penicillin treatment was found essential for this aim.[253] From these studies, penicillin, a bactericidal agent with activity against streptococci, became the drug of choice.[93] Group A streptococci resistant to penicillin have never to date been documented.

Efficacy studies against rheumatic fever per se were performed mainly in military populations with injectable penicillin. Only one inconclusive study was done in children.[211] These studies more recently have been subjected to meta-analysis,[203] with a relative risk of 0.20 (95% CI 0.11, 0.36; $p < .00001$) favoring the intervention and demonstrating that rheumatic fever can be prevented approximately 80 percent of the time. The ability of oral penicillin to eradicate streptococci in throats is not equal to the ability of injectable penicillin to do so.[23]

In the absence of clear direction from the published literature for the control of rheumatic fever in an endemic area with inadequate health care access, a cluster-randomized, school-based, controlled trial of sore throat clinics in schools using oral penicillin in New Zealand (>80,000 person-years of observation) was performed. Trained and highly supervised lay workers working with public health nurses were the main workforce. Over the 4-year study period, consent, participation, antibiotic

adherence, and retention rates remained high. The outcome suggested a clinically useful result, but with uncertainty about the effect size. Possible reasons for the failure to demonstrate a statistically significant reduction in rheumatic fever were persistent house crowding,[115] an inability to follow symptomatic siblings (who may have been at a control school) because of the school-based design, use of oral rather than injectable penicillin, or other reasons. Exclusion from school of streptococcal pharyngitis cases was not possible. A meta-analysis of published literature on community-based or school-based controlled studies to prevent first attacks of rheumatic fever revealed a relative risk of 0.62 (95% CI 0.45, 0.85; $p = .003$), which favors these interventions, suggesting approximately 40 percent efficacy.[135] The New Zealand study used supervised oral penicillin treatment[141]; the treatment regimen was unclear in the other studies.[54,61,185] Peer-reviewed guidelines for rheumatic fever control have led to population-based initiatives in New Zealand* that are ongoing at this time as a result of these endeavors.[16,125,126,136,139]

A comprehensive explanation for the decline in rheumatic fever in most areas of the developed world remains unclear. Improved housing after World War II, especially in Western Europe, improved access to health care, public health messages highlighting the desirability to manage sore throats appropriately, the availability of penicillin, and other factors have been cited (see section on epidemiology above).

Streptococcal pharyngeal infection should be identified in most situations before treatment is started. Guidelines using clinical parameters have evolved[52,125,137] and have been tested empirically to guide rational management.[163,164] Streptococcal pharyngeal infection can be diagnosed by throat culture or by using a rapid diagnostic antigen-detection kit.[33,92,93] Most tests have high specificity, so a patient with acute pharyngitis and a positive test result should be treated. Many of the tests have suboptimal sensitivity and should be confirmed by a throat culture.[93] One study found that in one third of individuals with false-negative rapid antigen-detection test results, streptococcal antibody titers increased subsequently, suggesting infection.[94]

One study supports the notion that primary preventive treatment with penicillin is effective even if started 9 days after the infection develops,[51] so physicians can wait 24 to 48 hours for verification of infection by recovery of group A β-hemolytic streptococci.[93] Delays should be minimized. In the New Zealand study discussed earlier, this finding has been challenged with 3 students developing acute rheumatic fever 5, 6, and 7 days after presenting with culture proven group A streptococcal pharyngitis.[141]

A dose of 1.2 million U of benzathine penicillin intramuscularly (0.6 million U if weight is ≤27 kg) usually is adequate treatment. Because of the discomfort and a possible, but small, risk associated with intramuscular penicillin,[113] oral penicillin V 250 mg two or three times per day for children ≤27 kg or 500 mg two or three times per day for adolescents and adults may be preferred. Amoxicillin[57,81,93,143,210] 50/mg/kg once per day (maximum 1 g/day) for 10 days is the other antibiotic of choice. Although of somewhat broader spectrum, it has the advantage of once-daily dosing, is relatively inexpensive, and the suspension is considered more palatable than penicillin V suspension.[93] Erythromycin estolate 20 to 40 mg/kg/day in two to four divided doses (maximum 1 g/day) may be used in patients who are allergic to penicillin. Erythromycin ethyl succinate 40 mg/kg/day two to four times per day (maximum 1 g/day) is an alternative therapy.[66] The latter macrolides have been superseded in many countries by azithromycin 12 mg/kg/day (maximum 500 mg for 5 days) or clarithromycin 15 mg/kg/day in two divided doses (maximum 250 mg two times per day for 10 days). Clindamycin 20 mg/kg/day divided in three doses (maximum 1.8 g/day for 10 days) is also an alternative for the penicillin allergic or a narrow-spectrum cephalosporin.[93]

All oral treatments, except azithromycin, should be given for 10 days.[93] Although certain new wider spectrum agents such as azithromycin have been administered in shorter courses with the desired streptococcal eradication, on the basis of penicillin's narrow spectrum of antimicrobial activity, the infrequency with which it produces adverse reactions, and its modest cost, it is the drug of choice for nonallergic patients.[93]

Reappearance of acute rheumatic fever in a specific geographic region should draw attention to therapeutic, preventive, and epidemiologic measures for control of the disease. A targeted approach to particularly high-risk population groups in schools may be cost-effective and efficacious.* Because treatment of pharyngitis seems likely to have contributed to the declining incidence of rheumatic fever, obtaining throat cultures (or a rapid antigen-detection test) and administering penicillin treatment, if positive, for group A streptococci, still are recommended in low-risk populations, although this recommendation is being challenged by some physicians.[163,164] In addition, a negative culture avoids unnecessarily prescribing antibiotics in the 70 to 80 percent of children with a sore throat attributable to viral pharyngitis, although clinical assessment may obviate having to obtain a throat culture.[164,209]

Prompt administration of antibiotic therapy may shorten the duration of symptoms in patients with group A β-hemolytic streptococcal pharyngitis.[195] Cultures should be used selectively in age groups in which rheumatic fever rarely occurs (e.g., <4 years of age or >20 years). Signs and symptoms usually not associated with streptococcal infection, such as simple coryza, hoarseness, cough, conjunctivitis, anterior stomatitis, and diarrhea,[93,164] may help target the approach in a low-risk population.

A follow-up throat culture taken after a course of treatment for streptococcal pharyngitis is not recommended routinely, unless the patient remains symptomatic or is from a family with a rheumatic member.[33] Such follow-up cultures probably identify long-term carriers

*Heart Foundation: http://www.heartfoundation.org.nz.

*References 11, 37, 61, 184, 200, 236.

for whom repeated courses of antibiotics generally are not indicated.[33] Streptococcal carriers seem to pose little threat to themselves regarding the development of sequelae from streptococcal infection or dissemination of the organism to people around them. When a symptomatic viral upper respiratory tract infection develops in such a carrier, distinguishing whether the group A streptococci isolated indicate a current streptococcal infection or identify that individual as a chronic carrier is usually impossible. In one study, only 43 percent of children with paired sera from whom group A streptococci were recovered showed a significant antibody response to one of two different streptococcal antibodies.[123]

Often, a reasonable approach is to administer a single course of therapy. Indications for obtaining cultures from household contacts vary according to circumstances.[66] Family contacts of high-risk patients should have a culture performed and receive treatment if the culture is positive.

In the era before penicillin, 75 percent of individuals developed a recurrence of acute rheumatic fever.[36] Continuous penicillin prophylaxis is well established in its ability to prevent recurrent attacks (Fig. 29-7), with intramuscular long-acting preparations being superior to oral twice-daily delivery.[89,148] Persistent worsening rheumatic heart disease is prevented.[152] Secondary prophylaxis is considered the most cost-effective management of acute rheumatic fever and its sequelae.[225]

The parenteral route has been shown to be more effective (1.2 million U of benzathine penicillin intramuscularly at 28-day intervals).[262] In a comprehensive study, children experienced a recurrence rate of only 0.4/100 patient-years of observation (Table 29-6). A Cochrane systematic review found an 87 to 90 percent reduction with parenteral penicillin in four studies.[147] An international study of allergic reactions to long-term benzathine penicillin prophylaxis found that the benefits of preventing recurrence far outweighed the risk for development of a serious allergic reaction.[113] In areas of particularly high risk, administration of benzathine penicillin every 21 days may be more efficacious, although this study was not performed systematically.[144] Serum levels of penicillin toward the end of the time can be unreliable,[121] although this decision should be offset against practicability, cost, and probable compliance.

The need for benzathine penicillin every 21 days was challenged in a carefully monitored, community-based program evaluation with high compliance rates.[103,217] On four weekly injections of penicillin, the penicillin failure rate per se was very low at 0.07/100 patient-years.[217] The program failure rate was 1.4/100 patient-years, with failure primarily resulting from nonadherence. This is in an environment endemic for rheumatic fever, where children had a 1:3 annual chance of having group A streptococci detected in their throats.[141] A study in Egypt[124] showed that two weekly injections of penicillin resulted in an almost 50 percent reduction in recurrences. This result occurred, however, in an environment in which the rate of recurrences was approximately 45 percent of cases in the four-weekly penicillin comparison arm, suggesting imperfect adherence to the treatment regimen. Data for the latter are not presented. A publication supporting the use of 1 percent lidocaine hydrochloride as a diluent for benzathine penicillin G to increase tolerability may be useful for increased program adherence.[7] Increased frequency of benzathine penicillin injections beyond those necessary will add complexity and cost to secondary prevention programs. Re-evaluation in the modern era is pressing.[225] Patients allergic to penicillin may be given erythromycin. Penicillin and sulfadiazine are oral regimens that have been studied for efficacy (see Table 29-6). Sulfadiazine is not readily available in the United States.[10] The lesser efficacy of oral regimens is related at least partly to compliance difficulties.

The risk for rheumatic fever occurring after a group A streptococcal infection increases from an attack rate of 1 to 3 percent with the first attack of streptococcal pharyngitis to 25 to 75 percent with subsequent attacks.[75] Patients who have had carditis are at increased risk for development of further carditis. Patients who have not had clinical carditis have considerably less risk for having cardiac involvement after a recurrence.[82,145] In the echocardiographic era, the dogma that a patient who escapes carditis in the first attack is highly likely to remain free of rheumatic heart disease, even if prophylaxis fails in subsequent attacks, has been challenged.[82,217]

The risk for recurrence depends on several other factors, such as the length of time since the most recent attack, multiple previous attacks, and the risk for acquiring streptococcal throat infections according to occupation or living circumstances.[36,228,259] If possible, the length of prophylaxis should be individualized. The suggested length ranges from a minimum of 5 years of prophylaxis to a maximum of lifelong prophylaxis.[59,93] This approach has been validated in a study from Chile.[26]

The New Zealand approach* to recurrence prevention has been in place in Auckland for more than 2 decades.[16,217] All patients, regardless of cardiac status, receive at least 10 years of prophylaxis or until they reach 21 years of age (see earlier details for recurrence prevention). Evaluation of criteria for discharge from prophylaxis revealed only two recurrences in this series, which occurred in teenagers inadvertently discharged after at least 5 years of prophylaxis. It was concluded that it is safe to discharge individuals with mild or no clinically evident carditis at the time of discharge, per the recommendations in this highly rheumatic fever endemic environment.[217] Recommended length of prophylaxis varies by authority.[218] Rigorous evaluation is lacking.

The American Heart Association has recently published updated recommendations for the use of prophylactic antibiotics for prevention of infective endocarditis, most notably no longer suggesting prophylaxis for patients with rheumatic heart disease.[261] Some exceptions are necessary, such as those with prosthetic valves or prosthetic material used in valve repair. Some other international scientific bodies have made similar recommendations.[101] However, this approach has not been followed in New Zealand, where rheumatic valvular disease

*Heart Foundation: http://www.heartfoundation.org.nz.

remains common in disadvantaged individuals[168] who in addition have important dental and periodontal disease.*[62]

CONCLUSION

Although having effective prophylaxis against a disease[161] for which the pathophysiology is understood incompletely and for which no pharmacologic cure exists is gratifying, rheumatic fever and its sequelae still occur in numerous young people, especially in the developing world and in disadvantaged populations in the developed world.[264] This rate is largely a reflection of complacency about rheumatic fever and rheumatic heart disease by physicians and health care funders, although it also is likely to reflect living conditions and health care access. Renewed educational efforts regarding prevention of rheumatic fever are needed by physicians and the public. The available preventive methods should be applied vigorously. Applying modern research tools may be beneficial.

CHAPTER 30

Mediastinitis

Morven S. Edwards

The mediastinum is the extrapleural portion of the thoracic cavity situated between the two pleural sacs. The superior and inferior portions are separated arbitrarily by a line extending from the lower manubrium to the fourth thoracic vertebra. The superior mediastinum contains the thymus gland, trachea, esophagus, and aortic arch. The inferior mediastinum is divided into the anterior compartment, containing lymphatic tissue and fat; the middle compartment, containing the heart, pericardium, aorta, bifurcation of the trachea, main bronchi, and numerous lymph nodes; and the posterior compartment, containing the esophagus, thoracic duct, descending aorta, and vagus nerve. *Mediastinitis* refers to inflammation of the tissues located in the mediastinum. Infections of the mediastinum are uncommon, but often they pose a serious threat to vital structures.

Acute mediastinitis is a fulminant, septic process, and chronic mediastinitis is an indolent infection that produces late symptoms caused by compression of adjacent structures. Acute mediastinitis is subclassified as (1) traumatic, occurring as a consequence of perforation of the esophagus; (2) infection extending to the mediastinum from adjacent structures; and (3) postoperative, usually occurring after thoracic surgery (Table 30-1).

ACUTE MEDIASTINITIS

Mediastinitis due to Esophageal Perforation

The esophagus is a thin-walled organ, and esophageal perforation is the most common cause of acute mediastinitis.[42] Perforation usually occurs at one of the three sites of anatomic narrowing of the esophagus: (1) the proximal end, located at the level of the cricopharyngeal muscle; (2) the midthoracic segment, where the aortic arch and left main stem bronchus indent the esophagus; or (3) the transdiaphragmatic segment. A correlation exists between the location of the perforation and the injury. Proximal perforations usually are caused by instrumentation or ingestion of a foreign body. The proximal segment is the narrowest, and perforations generally are located in the posterior wall, adjacent to the prevertebral and retrovisceral spaces. Perforations at the aortic arch usually are caused by ingested foreign bodies. Transdiaphragmatic perforations usually are spontaneous. In most such cases, a longitudinal tear occurs on the left posterolateral wall just above the cardia, where the esophagus has little connective tissue support and its intrinsic musculature is weak.

Retching or vomiting can generate sufficient force to cause esophageal perforation, also known as Boerhaave syndrome. Traumatic perforation can occur after blunt trauma, from ingestion of a foreign body, or as a complication of endoscopic or open surgical procedures. Ingestion of coins, teeth, and food particles such as corn chips as well as objects such as a toy soldier or the spring from a clothespin have caused mediastinitis.[17] Children with mediastinitis from erosion of the esophagus caused by a foreign body tend to have small and well-contained perforations. Sharp objects, such as pins and bone fragments, can cause immediate transmural penetration. More commonly, and especially when a blunt object is ingested, the foreign body becomes impacted in the esophagus.[39] Eventually, suppurative necrosis of the wall occurs, with symptoms occurring days, weeks, or months after the ingestion.[23]

Perforations from instrumentation can produce precipitous clinical deterioration during the procedure from transmural laceration.[42] Alternatively, a superficial tear can occur from which infection subsequently extends, and several hours or days can elapse between instrumentation and the onset of symptoms. Repair of esophageal atresia is a common condition associated with a tear of the esophagus in childhood. In one review, 7 of 41 infants had a clinically significant esophageal disruption requiring reoperation 1 to 18 days after repair of esophageal atresia.[6] Postoperative perforations of the esophagus usually represent infectious complications of anastomotic leaks occurring after esophageal resection or of esophageal-pleural fistulas that develop after thoracic surgery. Most of these infections do not become apparent until weeks or months after surgery.

Presenting findings of acute mediastinitis after perforation of the esophagus include neck and chest pain, respiratory distress, and dysphagia. Chills, a temperature of 37.8° C to 39° C (100° F to 102° F), and leukocytosis also are common. Infants can present with tachypnea, tachycardia, stridor, or a supplemental oxygen requirement. Some patients have a staccato breathing pattern characterized by an inspiratory halt with resumption of inspiration after a brief rest.[12] The onset of symptoms usually is abrupt, and the course is fulminant. Physical examination often reveals cervical tenderness and subcutaneous emphysema in patients with proximal perforations, whereas patients with perforations of the lower esophagus are more likely to have signs suggesting an acute abdominal catastrophe. Examination of the lung fields often shows nonspecific abnormalities. The Hamman sign (a "crunching" sound heard in synchrony with the heartbeat along the left sternal border or cardiac

II. Chronic mediastinitis

apex) is observed in approximately 50 percent of cases of mediastinal emphysema, but it also occurs with left pneumothorax, dilated esophagus, gastric dilation, bullous emphysema, and pneumoperitoneum. Children with chronically retained foreign bodies can present with respiratory signs suggestive of asthma or reflux.[9]

The principal findings on chest radiographs are a widened mediastinum, subcutaneous and mediastinal emphysema, and pleural effusions. Pleural effusions occur more commonly with perforations of the lower than the upper esophagus and usually involve the left side. Basilar or retrocardiac infiltrates ascribed to chemical pneumonitis can occur in the pulmonary segment adjacent to the site of perforation. Additional changes often include basilar atelectasis, pneumothorax, or a hydropneumothorax. Radiopaque foreign bodies can be detected with plain radiographs, but often they are seen better with mediastinal computed tomography (CT) or magnetic resonance imaging (MRI).

Gas in the soft tissues seen on radiography is highly suggestive of perforation of the esophagus if interpreted in the context of a compatible clinical presentation. Gas in the prevertebral tissue or superior mediastinum occurs most commonly with perforation of the upper esophagus. Other conditions, such as chest wall trauma or perforation of the trachea, also can cause mediastinal emphysema.

The diagnosis of acute mediastinitis caused by perforation of the esophagus often can be based on clinical coupled with radiographic findings. Contrast-enhanced CT or MRI can provide additional anatomic detail and confirmation of the diagnosis.[47] Findings include esophageal thickening, fluid collections in the mediastinum adjacent to the perforation, and extraluminal air.[1] Other routine laboratory tests are not helpful. Analysis of pleural fluid usually shows a sterile exudate early in the disease course. Pleural fluid amylase levels often are normal within the first 24 hours after perforation. After 24 hours, the pleural fluid amylase level is elevated disproportionately compared with serum levels. Esophagoscopy is unnecessary and is contraindicated except for removing a foreign body.

Surgical drainage and repair and antimicrobial therapy are indicated for large perforations, when there is communication with the pleural space or abdomen, when vascular erosion is a concern, and in the setting of underlying esophageal pathology. Nonsurgical management can be considered for children in whom the perforation is a small, well-contained lesion in the upper esophagus in the absence of an underlying esophageal pathologic process.[10,23] Supportive measures include intravenous fluid support, maintenance of an adequate airway, esophageal rest, and careful monitoring of vital functions. Blood and pleural fluid cultures should be obtained, but they usually are sterile except late in the course. Antimicrobial agents provided empirically should be directed against streptococci, staphylococci, and oral anaerobic bacteria.[5,7] Mortality rates can be high when recognition of the infection is delayed.[42]

Mediastinitis due to Extension of Infection from Adjacent Structures

The mediastinum is anatomically well situated for involvement when infection extends downward from the oropharynx. Fascial planes from the supraclavicular region and abdomen traverse the mediastinum, and the lymphatic duct is located in the mediastinum. The lung, situated laterally to the mediastinum, is a frequent locus of potentially serious infection. Despite its position as an anatomic crossroad, however, extension of infection to the mediastinum from adjacent structures occurs infrequently.

In the preantibiotic era, retropharyngeal or peritonsillar abscess, Ludwig angina, dental abscess, and other infections of the head and neck were common causes of acute mediastinitis.[14,46,53] Since the advent of penicillin, infections of the head and neck usually are contained at the site of origin. The principal spaces that serve as conduits to the mediastinum when these infections extend are the visceral division of the deep cervical fascia that envelops the esophagus, trachea, larynx, and thyroid gland and the carotid sheath, which extends from the base of the skull, passes through the posterior pharyngomaxillary space along the prevertebral fascia, and enters the chest. Mediastinitis can occur as a complication of retropharyngeal abscess, peritonsillar and dental abscesses, as well as mastoiditis, laryngectomy, mediastinotomy, tracheostomy, and surgery or trauma of the oropharynx. Mediastinitis can complicate placement of airway stents for management of tracheal or bronchial stenoses in children.[21]

Children have developed mediastinitis after incurring intraoral injuries caused by falling with an object such as a toothbrush in their mouths.[25] Infection spreads to the mediastinum through the retropharyngeal space. As noted earlier, sharp objects, such as fish bones, can perforate the esophagus, with resultant infection.[36] A penetrating wound to the oropharynx can be caused by falling on a sharp or pointed object such as a pencil. Mediastinitis rarely results in a complication of suppurative pleuropulmonary infection. Extension of infection from vertebrae, ribs, or sternum also is unusual. The main radiographic feature by plain chest radiograph is widening of the mediastinum. Imaging by contrast-enhanced cervicothoracic CT or MRI is crucial for establishing the

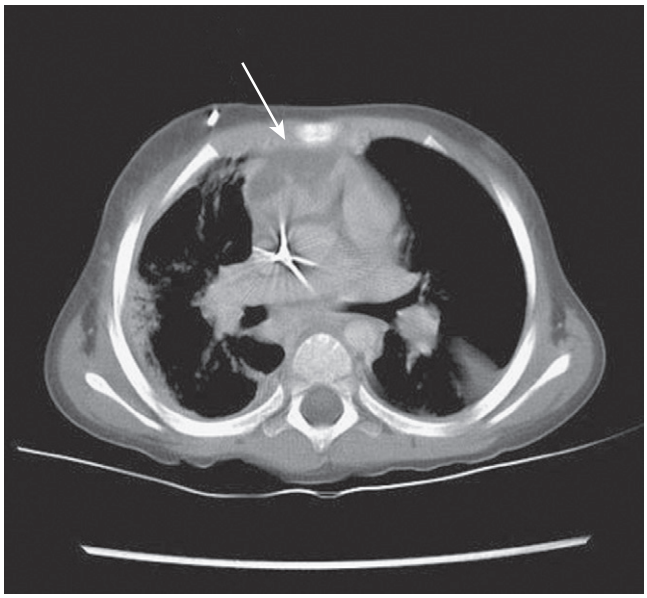

FIGURE 30-1 ■ Contrast-enhanced CT scan shows a 3 × 3-cm heterogeneous enhancing abscess *(arrow)* in the anterior mediastinum of a child acutely ill with *Streptococcus pneumoniae* bacteremia and pneumonia with empyema. Cultures from the mediastinal abscess at the time of surgical drainage were sterile.

diagnosis and can reveal heterogeneous infiltration, gas in tissues, abscesses, and fluid collections (Fig. 30-1).

The major bacteria responsible for suppurative infections that originate in the oral cavity and extend to the mediastinum are streptococci and anaerobic oral flora.[7,35] Methicillin-sensitive and methicillin-resistant *Staphylococcus aureus* (MRSA) should be considered potential pathogens, especially in mediastinitis complicating retropharyngeal abscess.[43,51] Mixed infection with aerobes and anaerobes should be anticipated when empirical therapy is initiated. Group A streptococcus is a common pathogen when the oropharynx is the original portal of entry. Other streptococci, including *Streptococcus anginosus* (formerly *S. milleri*) and group F streptococcus, are common isolates. Anaerobic bacteria, principally *Prevotella* spp., *Bacteroides* spp., *Fusobacterium* spp., and peptostreptococci, are the major anaerobic pathogens. Gram-negative aerobic bacteria, including *Pseudomonas aeruginosa*, *Serratia* spp., and *Neisseria* spp., are isolated less often.[28] Clindamycin often is regarded as the agent of choice for streptococci and anaerobes, although some authorities prefer other regimens, including penicillin plus metronidazole, cefoxitin, cefotetan, meropenem, or a β-lactam/β-lactamase inhibitor.[7,13] Consideration should be given to including vancomycin in empirical regimens for MRSA coverage until culture results are available.

Surgical drainage combined with appropriate antibiotic therapy is the cornerstone of treatment. Transcervical incisions usually are employed when spread to the superior mediastinum has occurred. Extension of the infection below the level of the fourth thoracic vertebra requires a parasternal or paravertebral approach, depending on whether the anterior or posterior mediastinum is involved.

Postoperative Mediastinitis

Sternal wound infections are an uncommon complication of median sternotomy for cardiac surgery in children.* The Centers for Disease Control and Prevention classifies surgical site infections in cardiac patients as superficial or deep wound infection, sternal osteomyelitis, or mediastinitis. Mediastinitis is a serious complication, with potential involvement of contiguous structures, including prosthetic valves, grafts, pericardium, lung, and chest wall. Contemporary incidence data for mediastinitis after pediatric cardiac surgery is 0.2 to 1.4 percent of procedures.[2,27,31,48] The incidence is higher after cardiac transplantation.[27] Postoperative wound infection is more often a complication of double-outlet right ventricle repair, truncus repair, atrial switch, or valvulatory or conduit procedures than of repair of atrial septal defect, ventricular septal defect, or tetralogy of Fallot.[38] Mediastinal infection has developed from an infection of a retained epicardial pacemaker lead.[19]

Some of the well-established risk factors for development of poststernotomy mediastinitis in adults are not applicable to children. Factors that are linked to risk for development of mediastinitis after median sternotomy in children are shown in Table 30-2.[2,22,31,48] Obesity and diabetes mellitus, which are risk associations in adults, have not been assessed as potential risk factors in more recent pediatric series. Factors not associated with risk for infection include emergency surgery or prior infection.[31] Intraoperative introduction of organisms is considered the source of most infections. Epidemics have been traced to operating room personnel, who can serve as the source of *S. aureus* or other bacteria.[15]

In three pediatric series, median age at diagnosis of mediastinitis after pediatric cardiac surgery ranged from 6 weeks to 3 years.[2,27,48] Median time to onset of infection after surgery was 10 to 14 days, with a range from 4 to 50 days. The time to infection after initial sternotomy was longer for infections caused by gram-positive organisms than for infections caused by gram-negative bacteria or fungi in one report.[48] The presenting features include erythema, purulent drainage or tenderness of the sternal incision, wound dehiscence, sternal instability, persistent or recurrent postoperative fever,

*References 2, 4, 27, 31, 38, 48.

and leukocytosis. A common clinical sequence is fever and systemic toxicity followed by signs of a sternal wound infection with cellulitis or purulent drainage. Imaging abnormalities include mediastinal soft tissue swelling, pleural effusion, and sternal dehiscence or erosion, but CT does not always reveal abnormalities.[33,52] Consideration should be given to use of MRI, when infection is suspected. Lack of compelling radiographic evidence of infection should not delay surgical drainage when clinical signs are evident.

Empirical antibiotic treatment should be initiated based on the expected pathogens and modified according to the results of blood and wound cultures. Approximately two thirds of infections are caused by gram-positive bacteria, one fourth by gram-negative bacteria, and the remainder by yeasts and fungi. The most frequent pathogen is *S. aureus*, which accounts for more than half of infections; coagulase-negative staphylococci and enterococci (including vancomycin-resistant isolates) constitute the remainder of the gram-positive isolates.[2,27,48] In adults, methicillin-resistant *S. aureus* mediastinitis is associated with higher rates of overall mortality, mediastinitis-related mortality, and treatment failure than infection caused by methicillin-sensitive *S. aureus*.[32]

Approximately half of children have associated bacteremia, and infection with *S. aureus* is an independent risk factor for development of bacteremic postoperative mediastinitis.[44] Among gram-negative organisms, *P. aeruginosa*, *Serratia* spp., and *Citrobacter* are common isolates. Infection is polymicrobial in one fourth of patients.[2,27,48] *Candida* spp. should be considered in any patient with infection of the mediastinum, particularly when broad-spectrum antimicrobial agents have been used.[8] Almost any microorganism gaining entry to the mediastinum theoretically can serve as the nidus for infection, and *Mycoplasma hominis*, *Ureaplasma urealyticum*, *Nocardia*, and *Aspergillus* all have been reported, albeit rarely.[16,26,30,50] Heart and lung transplant patients are prone to acquisition of infection with less common and more resistant pathogens, such as *Aspergillus fumigatus* and *Burkholderia cepacia*.[27] *M. fortuitum* can cause apparently culture-negative mediastinitis and has been reported in a child who had undergone a Fontan operation.[45]

Adequate surgical débridement is crucial to successful treatment of postoperative mediastinitis. Surgical procedures to reexplore the sternum should be undertaken and infected and devitalized tissue débrided. After wound débridement, continuous irrigation and vacuum-assisted closure and use of simple primary closed drainage has been an effective management option.[3,49] Open wound packing and delayed rectus abdominis flap, pectoralis muscle flap, or omental reconstruction is required in some children.[37,48] Pectoralis muscle flap has been an effective treatment even in neonates.[11,48] Early consultation with the plastic surgery and reconstructive team is advisable when sternal reconstruction is anticipated. Infection superficial to the sternum can be treated simply with incision, packing, and a short course of antibiotics, usually for 10 to 14 days. Systemic antibiotics must be given for at least 3 to 6 weeks for children with postoperative mediastinitis.

CHRONIC MEDIASTINITIS

Chronic mediastinitis histologically can be fibrosing or granulomatous. Both are rare conditions in which a definite cause often remains elusive. The clinical presentations are identical, and considerable overlap can occur in histologic findings. Fibrosing mediastinitis can be focal or diffuse; calcification within the lesion is observed more often when the process is focal. Some authors propose that mediastinal fibrosis represents the end stage of mediastinal granuloma, whereas others suggest that the two are distinct entities.[41] Fibrosing mediastinitis can be associated with a fibrotic process at another anatomic site, such as the retroperitoneum.

Chronic mediastinitis is rare in very young children but has been described in toddlers.[40] Many patients are asymptomatic, and the lesion initially is detected by routine chest radiographs showing a widened superior mediastinum near the tracheal bifurcation or the hilum with a lobulated configuration. Concomitant changes in the pulmonary parenchyma that are seen on chest radiograph vary. Common clinical presentations include recurrent pneumonia and hemoptysis.[20] Symptoms, when manifested, can reflect compression of adjacent structures, such as the superior vena cava, pulmonary vessels, esophagus, and tracheobronchial tree. Patients can present with low-grade fever, cough, pleuritic chest pain and dyspnea, with anemia and weight loss.[41]

When an inciting cause for chronic mediastinitis can be identified, it usually is linked to infection with *Histoplasma capsulatum*. Two types of mediastinal fibrosis caused by histoplasmosis are recognized. Mediastinal granuloma is caused by coalescence of a cluster of mediastinal lymph nodes to form an encapsulated mass that may be large and compress adjacent structures, especially the superior vena cava or esophagus. Surgical resection often is feasible but is advocated only when the obstruction is significant. Fibrosing mediastinitis is thought to result from an exuberant inflammatory response to *H. capsulatum* and to represent a resolved, rather than an active, infectious process. Less common causes of fibrosing mediastinitis include tuberculosis, blastomycosis, cryptococcosis, aspergillosis, zygomycosis, autoimmune disease, nocardiosis, actinomycosis, and lymphoma.*

The diagnostic evaluation of patients with possible chronic mediastinitis should include a chest radiograph and contrast-enhanced CT or MRI. A vascular imaging study may be required if there is evidence of venous or vena caval obstruction or if arterial involvement is present. Testing for tuberculosis and histoplasmosis serology should be obtained. Cultures of sputum for *Mycobacterium tuberculosis* and pathogenic fungi are rarely positive. Antigen assay for *H. capsulatum* using blood and urine usually is negative, and skin tests are not helpful. Complement-fixation titers usually exceed 1 : 8 in patients with chronic histoplasmosis.

Surgical resection can be associated with high morbidity rates but can be curative. Biopsy of the lesion by mediastinoscopy can exclude a malignant process and

*References 18, 24, 29, 34, 40, 41.

provide tissue for histopathologic evaluation. Antifungal therapy is not likely to affect resolution of the process when surgically excised tissue shows fungi consistent with *H. capsulatum* with sterile cultures. Dense fibrosis of mediastinal structures without a granulomatous component does not respond to antifungal treatment.

SECTION IV

CENTRAL NERVOUS SYSTEM INFECTIONS

CHAPTER 31

Bacterial Meningitis Beyond the Neonatal Period

Kwang Sik Kim

Bacterial meningitis is an inflammation of the meninges affecting the pia, the arachnoid, and the subarachnoid space that occurs in response to bacteria and bacterial products. A discussion of infections of neonates, including bacterial meningitis, is presented here, and infections of the central nervous system (CNS) caused by mycobacteria are discussed in other chapters.

INCIDENCE AND EPIDEMIOLOGY

Before the discovery and use of antibiotics, bacterial meningitis generally was fatal. Antibiotic therapy has dramatically improved the prognosis in patients with bacterial meningitis, although it continues to be a significant cause of morbidity and mortality in infants and children. The number of deaths attributed to many other infectious diseases in the United States decreased by 10-fold to 200-fold between 1935 and 1968, whereas the number of reported deaths caused by bacterial meningitis decreased by only half during the same period.[366,367]

The epidemiology of bacterial meningitis has changed by several recent preventive measures introduced since the early 1990s, such as introduction of the *Haemophilus influenzae* type b conjugate vaccine and the pneumococcal conjugate vaccine for infants and screening of pregnant women for group B streptococcus and intrapartum antibiotic prophylaxis since 1996.*

Before the widespread use of the *H. influenzae* type b conjugate vaccine, *H. influenzae* type b was the most common cause of bacterial meningitis in children in the United States, Canada, and Scandinavia, but this pattern was not universal. Davey and associates[89] reported that between 1968 and 1977, *Neisseria meningitidis* was the most common cause and *H. influenzae* type b was the second most common cause of bacterial meningitis for children and young adults in Great Britain. Data from 2001 showed that meningococcal meningitis accounted for 48 percent of meningitis in children in England.[90]

Studies in the 1970s and 1980s showed that three pathogens (*H. influenzae*, *Streptococcus pneumoniae*, and *N. meningitidis*) are predominant in infants, children, and young adults, whereas group B streptococcus, *Escherichia coli*, and *Listeria monocytogenes* are the most common bacteria causing meningitis in neonates. Between 1986 and 1995, the incidence of bacterial meningitis declined markedly, largely owing to the introduction of *H. influenzae* type b conjugate vaccines in infants. After the introduction of the heptavalent pneumococcal conjugate vaccine (PCV7), including pneumococcal serotypes 4, 6B, 9V, 14, 8C, 19F, and 23F, to infants in 2000, invasive pneumococcal disease in the United States declined by 75 percent among children younger than 5 years of age as well as by 31 percent among adults 65 years or older and in unvaccinated populations through herd immunity.[181,200]

In 1972, the Centers for Disease Control and Prevention (CDC) estimated that in the United States, 29,000 cases of meningitis were caused by *H. influenzae* type b, 4,800 cases were caused by *S. pneumoniae*, and 4,600 cases were caused by *N. meningitidis*. However, based on cases of bacterial meningitis from 2003 to 2007, an estimate of an average of 4,100 cases of bacterial meningitis, including 500 that were fatal, occurred annually in the United States during 2003 to 2007.[358]

Population-based studies in South Carolina, Minnesota, Vermont, and New Mexico in the 1970s suggested that the actual incidence of bacterial meningitis ranged from 5.4 to 7.3 cases per 100,000 population.[62,131-134] Studies reported from the CDC in 2011 indicated that the incidence of bacterial meningitis ranged from 6.91 cases per 100,000 population for children aged 2 to 23 months to 0.43 case per 100,000 population for adolescents aged 11 to 17 years (Table 31-1).[358]

A recent report of bacterial meningitis in the United States from 1998 to 2007 showed that the overall incidence of meningitis declined by 31 percent from 2.00 cases per 100,000 population in 1998 to 1999 to 1.38 cases per 100,000 population in 2006 to 2007, but the incidence remained unchanged in patients younger than 2 months of age (see Table 31-1).[358] The incidence of bacterial meningitis was highest for patients younger than 2 months of age and for black patients of any age. The median age of patients increased from 30.3 years during 1998 to 1999 to 41.9 years during 2006 to 2007, and this shift was significant, suggesting that the burden of bacterial meningitis is borne more by older adults. However, the case-fatality rate did not change significantly from 15.7 percent in 1997 to 1998 to 14.3 percent in 2006 to 2007.[358]

In 2003 to 2007 in the United States, the most frequent cause of bacterial meningitis in children younger than 2 months of age was group B streptococcus (86.1% of cases), and *N. meningitidis* caused 45.9 percent of cases

TABLE 31-2 **Pathogen-Based Incidence of Bacterial Meningitis in the United States, 1998-2007, per 100,000 Population**

Pathogen	1998-1999	2006-2007	Percent Change 2006-2007 vs. 1998-1999
S. pneumoniae	1.09	0.81	–26
N. meningitidis	0.44	0.19	–58
Group B streptococcus	0.24	0.25	4
H. influenzae	0.12	0.08	–35
L. monocytogenes	0.10	0.05	–46

From Thigpen MC, Whitney CG, Messonnier NE, et al. Bacterial meningitis in the United States 1998-2007. *N Engl J Med* 2011;**364**:2016–25.

among those 11 to 17 years of age. Among the other pediatric age groups, *S. pneumoniae* was the most common cause (Table 31-2).[358] The case-fatality rate was 6.9 percent among pediatric patients, and nearly 10 percent had underlying immunocompromising or chronic medical conditions. *E. coli* and *L. monocytogenes* are other common causes of meningitis in neonates 2 to 6 weeks of age.[358]

Epidemiology of Meningitis Caused by *Streptococcus pneumoniae*

S. pneumoniae is the most common pathogen causing bacterial meningitis in the United States. The risk for development of sepsis or meningitis caused by *S. pneumoniae* depends to some extent on the serotype with which the child is colonized and against which there is no opsonic antibody. Although 90 pneumococcal serotypes have been identified, invasive disease, including sepsis and meningitis, in children younger than 6 years old was associated most commonly with serotypes 14, 6B, 19F, 18C, 23F, 4, and 9V in the United States.[57] The 7-valent pneumococcal conjugate vaccine (PCV7), added to the national vaccination schedule in 2000, contains each of the just-mentioned most common strains.[67]

Nasopharyngeal colonization in children mainly depends on age (young age), crowding, attendance at daycare centers, and ethnicity (the Native American population). The serotype distribution of colonization isolates is by and large a reliable indicator for invasive disease, antibiotic resistance profiles, and potential vaccine coverage.[44] Daycare attendance, underlying disease, and lack of breast-feeding were risk factors for acquiring invasive pneumococcal infections in a large case-control study that included children from the United States and Canada.[228] Although cigarette smoking is a major risk factor for the development of invasive pneumococcal disease in adults, whether exposure to cigarette smoke increases the risk for developing systemic pneumococcal infection in children remains unclear.[271]

TABLE 31-3 **Age-Based Incidence of Pneumococcal Meningitis in the United States, 1998-2007, per 100,000 Population**

Age	1998-1999	2006-2007	Percent Change 2006-2007 vs. 1998-1999
2-23 mo	9.69	3.67	–62
2-10 yr	0.54	0.36	–34
11-17 yr	0.20	0.21	7
18-34 yr	0.40	0.27	–33

All ages	1.09	0.81	–26

From Thigpen MC, Whitney CG, Messonnier NE, et al. Bacterial meningitis in the United States 1998-2007. *N Engl J Med* 2011;**364**:2016–25.

In the prevaccine era (before 2000 in the United States), the age-specific incidence for pneumococcal meningitis was 21, 12, 6, 2, and 0.5 cases per 100,000 for the age groups 0 to 6 months, 7 to 12 months, 13 to 24 months, 25 to 60 months, and older than 60 months, respectively.[394] The overall incidence of *S. pneumoniae* meningitis, however, decreased by 26 percent from 1.09 cases per 100,000 population in 1998 to 1999 to 0.81 case per 100,000 based on the recent report of bacterial meningitis in the United States.[358] This decline included a decrease of 62 percent among children 2 to 23 months of age (Table 31-3). The incidence of meningitis from *S. pneumoniae* PCV7 serotypes declined by 92 percent from 0.61 case per 100,000 population in 1998 to 1999 to 0.05 case per 100,000 population in 2006 to 2007. However, the incidence of meningitis from non-PCV7 serotypes increased by 62 percent from 0.48 case per 100,000 population in 1998 to 1999 to 0.77 case per 100,000 population in 2006 to 2007.[358] Meningitis with *S. pneumoniae* had a case-fatality rate of 17.9 percent in 1998 to 1999 and 14.7 percent in 2006 to 2007.[358]

Among children ages 2 months to 10 years, *S. pneumoniae* was the most common cause of bacterial meningitis. PCV7 serotypes accounted for 15.5 percent of the pediatric cases overall and 13.0 percent of cases in the 2- to 23-month age groups. The case-fatality rates were similar among children infected with PCV7 isolates and those infected with non-PCV7 isolates (10.7% and 7.6%, respectively). Use of PCV7 also reduced invasive pneumococcal disease including meningitis among unvaccinated populations through herd immunity (see Table 31-3).[200] PCV13 serotypes (PCV7 serotypes plus serotypes 1, 3, 5, 6A, 7F, and 19A) accounted for 60.0 percent of cases in children between 2 and 23 months of age and 57.2 percent in children of any age. PCV7 and PCV13 serotypes accounted for 16.0 and 41.6 percent of the adult meningitis cases, respectively.[358] The overall fatality rate was 16.4 percent, and the rate increased linearly with increasing age (8.9% among patients 18 to 34 years of age to 22.7% among those 65 years and older, $p<.001$).[358] Vaccine serotype coverages by PCV7 and PCV13 are less in European and other countries than those in the United States.[108] Surveys of nasopharyngeal carriage of *S. pneumoniae* in Australia revealed that the percentages of serotypes included in PCV13 were 40 percent in 2- to 15-year-old children and 29 percent in adults.[236]

Pneumococcal infections generally occur sporadically. Household contacts of a patient with pneumococcal disease are not considered to be at increased risk for acquiring secondary infection. The occurrence of concurrent pneumococcal disease (meningitis and bacteremia) in the household setting has been reported, however.[19,332] Although uncommon in the United States, *S. pneumoniae* has been associated with epidemics in locations such as Northern Ghana.[226]

The incidence of systemic infection with penicillin-resistant *S. pneumoniae* has been increasing steadily worldwide since it first was reported in Australia in the 1960s.[173] Systemic infection with penicillin-resistant pneumococci has become an increasing problem in the United States since the mid 1980s.[345,352] In 1995, a CDC multistate surveillance study showed that 35 percent of cerebrospinal fluid (CSF) isolates of *S. pneumoniae* were resistant to penicillin.[319]

The first report of meningitis caused by resistant pneumococci was published in 1974,[264] and numerous case reports appeared subsequently. Patients with systemic infections caused by penicillin-resistant pneumococci were more likely to have received a course of antibiotics within 1 month before acquiring their infection than were matched control subjects who had infections caused by pneumococci but whose isolates were susceptible to penicillin.[352]

By 1998, CDC surveillance of multiple areas around the United States found that 24 percent of pneumococcal isolates associated with invasive infections were nonsusceptible to penicillin; 14 percent of isolates were nonsusceptible to cefotaxime.[386] As with many studies, rates of resistance were higher among children younger than 5 years old. In contrast, penicillin- and cefotaxime-nonsusceptible pneumococcal isolates were 10.5 and 8.7 percent, respectively, in 2010.[358] In a prospective study involving eight children's hospitals nationwide during a 6-year period starting September 1993, a significant increase in the proportion of isolates nonsusceptible to penicillin or ceftriaxone was found. In the sixth year of the study ending August 1998, 37 percent and 11 percent of invasive isolates were nonsusceptible to penicillin and ceftriaxone, respectively.[192] Isolates of penicillin-resistant and third-generation cephalosporin-resistant *S. pneumoniae* have been recovered in other regions of the world as well.* Treatment failures in patients with *S. pneumoniae* meningitis resistant to penicillin and third-generation cephalosporins have led to changes in the empirical therapy of suspected bacterial meningitis, as discussed in the section on treatment.[140,205,335,362]

Data from the Active Bacterial Core Surveillance of the Emerging Infections Program Network after introduction of the 7-valent pneumococcal conjugate vaccine showed an 87 percent decrease in rates of antibiotic-resistant disease by vaccine serotypes.[216] These results show that rates of invasive pneumococcal disease with penicillin-nonsusceptible strains and strains nonsusceptible to multiple antibiotics "peaked in 1999 and decreased by 2004."[216] In children younger than 2 years old, invasive pneumococcal disease with penicillin-nonsusceptible strains decreased from 70.3 to 13.1 cases per 100,000.[216] The proportion of disease caused by penicillin-nonsusceptible strains varied by location within the United States from 9.4 percent in California to 29.5 percent in Tennessee.[216] The incidence of invasive *S. pneumoniae* disease caused by cefotaxime-resistant *S. pneumoniae* strains increased in children younger than 2 years of age, however, in the postvaccination period, from approximately 10 percent in 1999 to almost 15 percent in 2003.[216] The decreases in disease caused by vaccine-type *S. pneumoniae* strains were coupled with an increase in nonvaccine serotype *S. pneumoniae* strains, especially with serotype 19A (increased from 2.0 to 8.3 cases per 100,000).[216,361]

Recent data from 1998 to 2009 from continuous surveillance of invasive pneumococcal disease in eight geographic areas of the United States indicate that reductions in rates ranged by site from 19.0 to 29.9 cases per 100,000 population during 1998 to 1999 to 11.2 to 18.0 cases per 100,000 population during 2009 (rate reduction of 5.1 to 15.3 cases per 100,000 population).[302] Reductions among children aged younger than 5 years ranged from 35.7 to 117.2 cases per 100,000 population across the sites. Reductions in rates due to PCV7 were seen in all age groups and at all sites, ranging from 12.0 to 21.4 cases per 100,000 population during 1998 to 1999 to less than 2.0 cases per 100,000 population during 2009 (92% to 98% reductions). Serotype 19A rates ranged from 0.4 to 1.5 cases per 100,000 population during 1998 to 1999 to 1.3 to 3.4 cases per 100,000 population during 2009 (rate difference of 0.9 to 2.8 cases per 100,000 population). Rates due to all other serotypes ranged from 6.3 to 10.3 cases per 100,000 population during 1998 to 1999 to 8.3 to 13.6 cases per 100,000 population during 2009 (rate difference of –0.04 to 5.67 cases per 100,000 population). Across the sites, the greatest increases were seen in the 50- to 64-year and older than 65-year age groups.[302]

*References 94, 137, 251, 298, 377.

Epidemiology of Meningococcal Meningitis

In the United States, the incidence of *N. meningitidis* meningitis decreased by 58 percent from 0.44 case per 100,000 population in 1998 to 1999 to 0.19 case per 100,000 population in 2006 to 2007 (see Table 31-2).[358] The rates of meningococcal meningitis caused by serogroups B, C, and Y declined by 55 percent. Meningitis with *N. meningitidis* had a case-fatality rate of 10.1 percent. *N. meningitidis* remained a major cause of bacterial meningitis among older children and young adults between 11 to 17 years of age (45.9% of cases), despite the fact that rates declined significantly between 1997 and 2007. Because the declines were similar among all major serogroups and because quadrivalent meningococcal vaccines (A, C, Y, and W135) do not include serogroup B, these declines are not likely from a vaccine effect.[358] Serogroups B, C, and Y were most commonly identified (59.1%, 21.0%, and 11.4% of cases, respectively) in meningococcal isolates. Serogroup B caused 70.5 percent of the cases among children younger than 11 years of age. Serogroups included in quadrivalent meningococcal vaccines accounted for 66.7 percent of infections among children 11 to 17 years of age. Serogroups B and C were the predominant causes of meningococcal meningitis among adults 18 to 34 years of age, accounting for 34.4 and 45.9 percent of cases, respectively, whereas in adults 35 years of age or older, serogroups B and Y were the most common, each serogroup accounting for 30.4 percent of cases.[358] As the proportion of children receiving quadrivalent meningococcal vaccines continues to increase, additional reductions in the incidence of meningococcal disease are likely to occur (Fig. 31-1).

From 1990 to 2002 in the United States, mortality rates for meningococcal disease were 0.1 deaths per 100,000 population per year, with 58 percent of deaths occurring among individuals younger than 25 years old. Infants had a higher mortality rate than that of individuals in different age groups, but they experienced a decline from 1.3 deaths per 100,000 in 1990 to 0.42 deaths per 100,000 population in 2002.[327] Meningococcal disease mortality rates increased each year in individuals between the ages of 10 and 19 years, which was followed by a decline in mortality rates in the years following and throughout most of adulthood.[327]

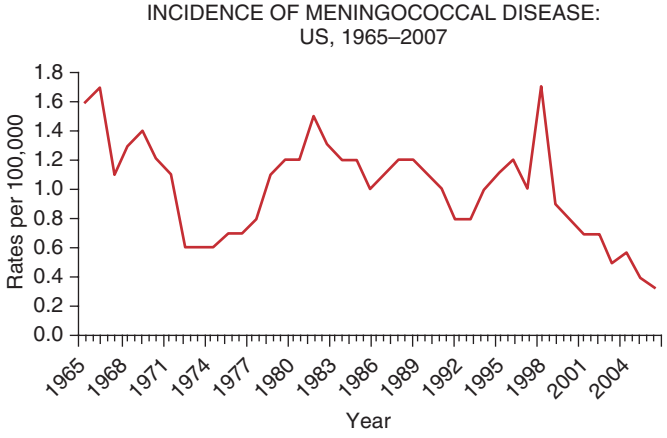

FIGURE 31-1 ■ Trends in annual incidence of invasive *N. meningitidis* disease in the United States, 1965-2007. (See companion website on Expert Consult for a color version of this figure.) (Data based on Active Bacterial Core Surveillance Report, CDC.)

In the United States, in the 1990s, serogroup Y became more common among older patients and caused more pneumonia than did the other serogroups. The overall incidence of serogroup Y infection increased from 2 percent during 1989 to 1991 to 37 percent during 1997 to 2002.[69] A study of the epidemiology of meningococcal disease in New York City from 1989 to 2000 revealed a threefold decrease in rates of serogroup B disease and almost no cases in children younger than 5 years old. The authors noted the coincident increase in the use of *H. influenzae* type b conjugate vaccine and postulated the existence of a possible correlation.[254] CDC data reveal that 75 percent of meningococcal infections in individuals older than 11 years of age are caused by serogroups C, Y, and W-135, all of which are included in the newly available conjugate vaccine. An increased risk for contracting meningococcal infection also exists in college students, especially freshmen who reside on campus in dormitories.[176]

The meningococcus is pathogenic only in humans. The carriage rate for *N. meningitidis* in the civilian population has been estimated at various times to range from 1 to 15 percent. Carriage rates in military personnel during epidemic periods have been considerably greater. Meningococcal carriers generally are adults (>21 years old) who harbor the organism for months, and meningococcus colonizes the nasopharynx asymptomatically in up to 40 percent of the adult population.[351]

No correlation has been noted between meningococcal meningitis and crowding within households, but disease seems to be more prevalent in urban than in rural areas. In a civilian population, meningococcal meningitis generally is a disease of children and young adults who have been exposed to an adult carrier, usually in the same family, or to individuals with disease or who are carrying the organism in a daycare setting. The estimated likelihood of severe meningococcal disease in family contacts occurring simultaneously with the first case is 1 percent.[223] The rate is 1000-fold greater than the risk in the community. The risk of meningitis being acquired in daycare center contacts of children with meningococcal disease is 1 per 1000.

Another change in the epidemiology of meningococcal disease in the United States relates to the increasing number of outbreaks (>10 cases per 100,000 population during 3 months), generally caused by serogroup C. Although these outbreaks account for only 2 to 3 percent of the total number of cases, they cause tremendous public concern and anxiety, which frequently result in misunderstanding of the nature of an outbreak by the media and the public.[184]

An otherwise unprecedented outbreak of meningococcal disease occurred in a sixth-grade elementary school classroom.[113] Five children from a class of 24 developed meningococcal meningitis. In addition, two siblings of one of the index patients also developed meningococcal infection. Detailed epidemiologic investigation suggested that close contact in the classroom (nose-to-nose

distances of ≤34 inches) correlated with an increased rate of carriage of *N. meningitidis* and with an increased risk for development of invasive meningococcal disease.

Major outbreaks of meningococcal meningitis have occurred worldwide. In the late 1980s and early 1990s, major epidemics of meningococcal meningitis caused by a specific clone (III-1) of serogroup A *N. meningitidis* occurred throughout sub-Saharan Africa.[2,166,170,286,310] The origins of a pandemic spread of clone III-1 were traced to epidemics in Asia in the early 1980s, with spread through the Near East.[1] An outbreak occurred during the annual pilgrimage to Mecca in 1987,[252,253] with pilgrims carrying clones back to their countries of origin, including the United States and the United Kingdom. Epidemics of closely related strains of clone III-1 serogroup A meningococcal meningitis occurred in the Sudan,[310] Ethiopia,[170] and Chad in 1988[253] and in Kenya[286] in 1989. A report in 1992 described an epidemic of clone III-1 in the Central African Republic in an area traditionally outside the "meningitis belt."[166] These epidemics generally begin during the dry season and decline at onset of the rainy season. According to the World Health Organization, "in major African epidemics, attack rates range from 100 to 800 per 100,000 population, but individual communities have reported rates as high as 1000 per 100,000."[245] Major outbreaks have occurred in Brazil,[96] in Finland,[277] and at multiple sites in Africa.[387] A clonal outbreak of serogroup W135 (ET-37ST-11 clonal complex) occurred in 2000 among Hajj pilgrims returning to Europe from Saudi Arabia. In 2001, outbreaks with serogroup W135 also occurred in Niger and Burkina Faso.[350]

Shifts within a community or within a country as a whole from one serogroup to another also are associated with an increased incidence of disease for several years after the new serogroup is introduced into the community.[303] The mechanisms underlying the changing patterns of meningococcal serogroups that cause diseases are unknown.

Protection from meningococcal infection depends on a functional complement system as well as the humoral antibody response. The serum bactericidal activity assay (SBA), which measures killing of *N. meningitidis* in the presence of specific antibodies and addition of complement is the standard immunologic correlate of protection. SBA titers of 4 or higher with the use of human complement (or 8 or higher with the use of rabbit complement) are considered protection against subsequent diseases.[22] Meningococcal infections occur more frequently in patients with a deficiency of the terminal components (C5-C9) of the complement system, and the risk for developing meningococcal infection in persons with deficiency of complement factor C5-C9 is approximately 600-fold higher compared with the general population.[54,107,126,231,311] More recently, an increased risk for contracting meningococcal meningitis has been reported in individuals with an inherited deficiency of C9[263] and with properdin deficiency.[340] Individuals with a complement-depleting underlying illness also are at particular risk for acquiring invasive diseases.[282] Screening for complement deficiency in pediatric patients with meningococcal disease is recommended.[224]

Epidemiology of *Haemophilus influenzae* Meningitis

The most dramatic change in the epidemiology of bacterial meningitis since the advent of antibiotics has occurred in the past 2 decades as a result of licensure of conjugate vaccines against *H. influenzae* type b.[68,238,276,319,358] The first vaccine available was *H. influenzae* type b capsular polysaccharide (polyribosylribitol) phosphate [PRP], which was licensed in April 1985 for use in children 18 to 59 months of age. Subsequently, vaccines with improved immunogenicity for children of younger ages were developed by covalently linking the capsular polysaccharide with protein antigens. In October 1990, the first conjugate, PRP diphtheria CRM_{197} protein conjugate (HbOC), was approved for infant use. In 1991, the Advisory Committee on Immunization Practices (ACIP) and the American Academy of Pediatrics (AAP) recommended universal infant immunization at 2, 4, and 6 months of age with either HbOC or PRP-meningococcal protein conjugate (PRP-OMP) vaccines.[8,63] Currently, four different conjugate vaccine preparations exist: PRP-CRM (HbOC), PRP-OMP, PRP-T (tetanus toxoid), and PRP-D (diphtheria toxoid), which is not licensed in the United States.[382]

Before universal vaccination was initiated, the incidence of *H. influenzae* meningitis varied worldwide. The incidence of *H. influenzae* meningitis in Scandinavian children younger than 5 years old averaged 16 to 28 cases per 100,000 children from 1975 to 1984.[278] The incidence of *H. influenzae* type b meningitis in three Pacific Island countries was 70 to 84 cases per 100,000 children younger than 5 years old in 2003[306] and 67 to 158 cases per 100,000 in Indonesian children younger than 5 years old in 1998 to 2002.[153] The incidence of *H. influenzae* meningitis in the Netherlands was 22 cases per 100,000 children younger than 5 years old.[367] A universal vaccination program in the Netherlands led to a marked decrease in the incidence, with six reported cases of meningitis caused by *H. influenzae* in a 1-year period after implementation of universal vaccination of infants compared with 34 cases per 100,000 children in a 1-year period before vaccination.[369]

The incidence of *H. influenzae* meningitis is markedly higher in nonindustrialized populations. Before the vaccination era, Alaskan Eskimos had an annual incidence of 282 cases per 100,000 children younger than 5 years of age.[380] The Navajo and White Mountain Apache Native Americans had a much higher incidence compared with that of Native Americans in other regions of the United States,[84,234] and the incidence among Australian Aboriginals and among certain African populations, such as those in Gambia and Senegal, was 3 to 10 times higher than that of populations in the United States and Europe.[40,156,174] The incidence of *H. influenzae* meningitis was decreased in Gambia from more than 60 cases per 100,000 children to none per 100,000 in children younger than 5 years old after implementation of *Haemophilus influenzae* type b vaccination in May 1997.[6]

Good epidemiologic data concerning the incidence of *H. influenzae* infection are, however, lacking in many other areas of the world. Measuring the extent of *H.*

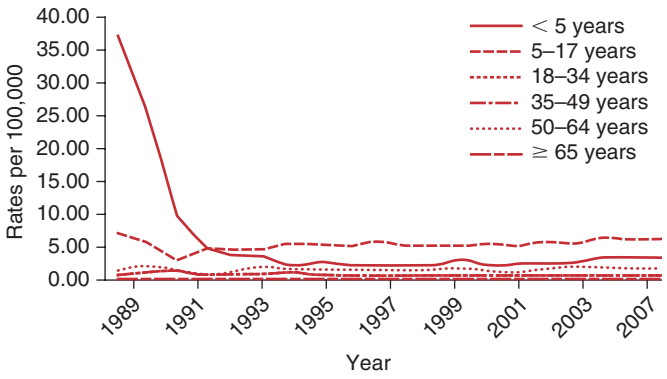

FIGURE 31-2 ■ Trends in incidence of invasive *H. influenzae* disease, by age group in the United States, 1989-2008. (See companion website on Expert Consult for a color version of this figure.) (From MacNeil JR, Cohn AC, Farley M, et al. Current epidemiology and trends in invasive *Haemophilus influenzae* diseases—United States, 1989-2008. *Clin Infect Dis* 2011;**53**:1230–6.)

influenzae disease often is difficult, time consuming, and expensive. In an attempt to decrease complexity, cost, and time required to collect data concerning the incidence of *H. influenzae* infection, the *Haemophilus influenzae* type b Rapid Assessment Tool was developed. More and more countries are using such tools to estimate the local *H. influenzae* disease burden and to help determine the need for implementation of a local vaccination program.[382]

In one study, the incidence of *H. influenzae* meningitis was 3.5-fold higher in blacks than in whites, but this distribution of cases seemed to be related more closely to poverty than to race.[131] In whites, no increase in incidence occurred in overcrowded households, but the incidence was higher in rural than in urban areas, which allowed the postulation that the increased incidence in rural whites and in blacks was related to lack of access to early medical care.[131]

The *Haemophilus Influenzae* Study Group[5] noted that the number of cases of *H. influenzae* meningitis in children younger than 5 years old reported through the National Bacterial Meningitis Reporting System began declining rapidly in 1988. In another CDC surveillance project conducted from 1989 to 1997, the race-adjusted incidence of invasive *H. influenzae* type b disease among children younger than age 5 years declined from 34.0 to 0.4 per 100,000, a 99 percent reduction (Fig. 31-2).[66,238] A report from Active Bacterial Core Surveillance sites during 1998 to 2007 indicated that small increases in the incidence of serotypes a, e, and f were observed, and the largest of these increases was in serotype f and was primarily among adults aged 18 years or older.[358]

The overall incidence of *H. influenzae* meningitis decreased by 35 percent between 1998 and 1999 and 2006 and 2007, from 0.12 cases per 100,000 population to 0.08 cases per 100,000 population (see Table 31-2); 9.4 percent of the cases were caused by serotype b.[358] The epidemiology of invasive *H. influenzae* disease in the post–*H. influenzae* type b vaccine era seems to be shifting from *H. influenzae* type b in children toward non–type b strains in older individuals.[358] For example, among adult cases of *H. influenzae* meningitis, a majority (73.8%) of the *H. influenzae* isolates were not typable whereas serotypes e and f were the most common serotypes identified (with each found in 11.5% of cases). The case-fatality rates were significantly higher among adults with typable *H. influenzae* than among cases from nontypable *H. influenzae* (18.8% vs. 2.2%, $p = .02$).[358]

Schoendorf and colleagues[321] evaluated national trends in mortality from *H. influenzae* meningitis from 1980 to 1991. From 1980 through 1987, mortality rates from *H. influenzae* meningitis decreased an average of 8.5 percent a year, from 1.72 per 100,000 children in 1980 to 0.94 per 100,000 children in 1987. From 1988 to 1991, mortality rates decreased an average of 48 percent a year, with a death rate of 0.11 per 100,000 children in 1991. The estimated case-fatality rate for *H. influenzae* meningitis was 3.3 percent from 1980 to 1987 and 2.3 percent from 1988 to 1991. In comparison, mortality rates from *S. pneumoniae* decreased 10 percent annually from 1980 to 1987 and 3 percent annually from 1988 to 1991. Similarly, mortality rates from meningococcal meningitis decreased by 13 percent annually from 1980 to 1987 and 12 percent annually from 1988 to 1991.

The dramatic decrease in the incidence of *H. influenzae* meningitis probably has been affected by several factors. The precipitous drop that occurred shortly after universal immunization of infants strongly suggests that this practice has affected the epidemiology of this disease. Conjugate vaccination protects against nasopharyngeal colonization,[259] decreasing the carriage rate of *H. influenzae* type b and diminishing the reservoir for transmission and providing immunity from infection. These factors would also lessen the likelihood of development of infection in unvaccinated populations through herd immunity. Other changes in medical practice, such as the widespread use of outpatient antibiotics and improvements in supportive care, may have some effect, as shown by the decrease in case-fatality rates for *H. influenzae* meningitis, the steady decrease in mortality rates before vaccination, and the decrease in instances of meningococcal and pneumococcal disease.

The risk for spread of severe *H. influenzae* illness among household contacts of patients with *H. influenzae* meningitis was studied prospectively in 19 states.[378] The risk in children younger than 1 year of age was 6 percent; in children younger than 4 years, 2.1 percent; and in children younger than 6 years, 0.5 percent. The risk for *H. influenzae* disease occurring in household contacts younger than 6 years old is similar to the risk for secondary meningococcal disease occurring in all household contacts, indicating a need for effective antimicrobial prophylaxis. Spread of *H. influenzae* disease in daycare centers also is well documented.[30,158,244,379] The precise risk for acquiring secondary *H. influenzae* type b infection in daycare centers is unclear.

Recurrent invasive *H. influenzae* type b disease has been reported. Detailed studies suggest that age and high incidence of disease alone are not the only factors contributing to the recurrence of the disease.[53] Patients who have recurrent disease caused by *H. influenzae* type b may represent a subset of a population with unusual disease susceptibility. In addition, children who develop invasive infection caused by *H. influenzae* type b after receiving appropriate conjugate vaccine frequently have subnormal immunoglobulin concentrations and should undergo immune evaluation.[180]

PATHOPHYSIOLOGY

Organisms Encountered

Almost all microorganisms that are pathogenic to humans have the potential to cause meningitis, but a relatively small number of pathogens (i.e., group B streptococcus, *E. coli*, *L. monocytogenes*, *H. influenzae*, *S. pneumoniae*, and *N. meningitidis*) account for most cases of acute bacterial meningitis in neonates and children.[199,200] The reasons for this association remain incompletely understood. In immunocompromised hosts, infection with other organisms may occur. The specific organism sometimes may be predicted on the basis of the type of deficit that is present in the host.

Routes of Infection

Bacterial infection of the normally sterile leptomeningeal spaces can occur from hematogenous spread, direct extension from paranasal and dental infections as well as skull base fracture, direct implantation (e.g., after surgery, cochlear implant), or rarely secondary to infections in the epidural or subdural spaces.[198-200] Bacterial meningitis in children with otitis media generally follows bacteremia, although direct invasion of the meninges may occur as a complication of otitis media.[198]

The meninges are seeded with microorganisms during a bacteremic period. Bacterial meningitis has been induced in infant rats[255] and monkeys[336] after intranasal inoculation of *H. influenzae* type b. Bacteremia developed hours before meningitis could be detected histologically, a finding that supports the concept that meningitis follows hematogenous dissemination from nasopharyngeal colonization or infection. Marginating bacteria could be detected by fluorescent staining initially in the lateral and dorsal longitudinal (sagittal) sinuses and subsequently spread to the leptomeninges. Several lines of evidence from human cases of group B streptococcus and *E. coli* meningitis and animal models of experimental hematogenous meningitis, however, reveal that cerebral capillaries are the portal of entry into the brain for circulating group B streptococcus and *E. coli*.[198-200]

Meningitis can also develop after bacterial invasion from a contiguous focus of infection, as in infection of the mastoid or paranasal sinuses or as a complication of otitis media. For example, *S. pneumoniae* has been shown to enter the CNS through a nonhematogenous route in experimental animals after intranasal infection and otitis media.[198] Fracture through the paranasal sinuses as a result of head trauma may precede development of meningitis caused by *S. pneumoniae* and *H. influenzae*, which may be recurrent. Direct invasion also may occur in individuals with dermoid sinus tracts or meningomyeloceles, when a direct communication between the skin and the meninges is present. In this setting, infection usually is produced by organisms found on the skin. Recurrent meningitis has been reported in patients with basiethmoidal encephaloceles[348] or a congenital defect in the stapedial footplate.[179] Surgical obliteration of the fistula with temporal muscle and fascia prevented the recurrence of meningitis. Meningitis also may develop subsequent to osteomyelitis of the skull or vertebral column. Rarely, meningitis may develop in the normal host with commensal microorganisms after having a tooth extraction or getting dental fillings.[79,328]

Neurosurgical procedures, particularly procedures designed for diversion of CSF in children who have hydrocephalus, may lead to development of meningitis. A chemical meningitis also may occur after neurosurgical procedures, especially procedures involving the posterior fossa.[130] In these patients, evidence of inflammation develops rapidly with elevation of temperature occurring on the first postoperative day.

Infection of the CNS may result from environmental contamination or manipulation. Meningeal infection may be acquired in utero transplacentally or during delivery through contact with the cervix or vaginal canal, which may be colonized with a variety of organisms, particularly group B streptococci, *E. coli*, and *L. monocytogenes*.[7,23,198-200] A neonate, a patient with cystic fibrosis, or a burned child may develop septicemia and meningitis as a result of persistent heavy colonization with *Staphylococcus aureus*. A humidified atmosphere promotes the colonization and growth of such organisms as *Serratia marcescens* and *Pseudomonas aeruginosa*. Placing a patient in this setting leads to an increased frequency of infection with these organisms. Indwelling catheters can predispose a patient to infection by bacterial (and fungal) organisms that generally are of low virulence in the normal host.

PATHOGENESIS

Most cases of bacterial meningitis develop through four steps: (1) colonization of the mucosal membranes such as upper respiratory or gastrointestinal tract, (2) invasion of the blood from the mucosal colonization, (3) traversal of the blood-brain barrier, and (4) inflammation of the meninges and brain.[198,199] Less commonly, infection of the leptomeninges can occur by contiguous spread or hematogenous dissemination from another remote site.

Mucosal Colonization

Most meningitis-causing bacteria colonize the mucosal membranes of the nasopharynx (*S. pneumoniae*, *N. meningitidis*, and *H. influenzae*) and gastrointestinal tract (*E. coli* and *L. monocytogenes*).[44,54,199,351] This attachment is mediated by specific microbial cell surface components and affected by co-colonization with other microorganisms and host immune response.

Several pneumococcal factors have been shown to enhance nasopharyngeal colonization and binding to nasopharyngeal epithelium: pneumococcal phosphorylcholine, IgA1-protease, capsular switching, pneumolysin, pneumococcal surface protein (Psp) C (also known as choline binding protein [CbpA]), pneumococcal surface adhesin A (PsaA), pneumococcal adherence and virulence factor A (PavA), neuraminidase A (NanA), and pili. Additionally, prior exposure to influenza virus has been associated with increased colonization and secondary invasive pneumococcal disease.[44,199,385] Pneumococcal phosphorylcholine binds to the platelet-activating factor (PAF)

receptor on activated host epithelial cells,[44] whereas the PspC binds to epithelial polymeric immunoglobulin receptor (pIgR).[395] The pIgRs are expressed in a decreasing gradient from the upper to lower respiratory tract, whereas the opposite pattern of expression is observed for the PAF receptor, suggesting that pIgR serves mainly as a pneumococcal receptor for the nasopharynx but the PAF receptor facilitates attachment and invasion of the pulmonary epithelium.[44]

N. meningitidis strains use IgA1 protease, pili, and outer membrane proteins Opa, Opc, and porin A and B for binding to cell surface receptors on nasopharyngeal mucosal cells[54,97,199] and apparently are transported across specialized cells within phagocytic vacuoles.[349] Human embryonic antigen cell adhesion molecules (CEACAMs or CD66) are cell-surface molecules in nasopharyngeal epithelial cells that interact with meningococcal Opa proteins.[54]

Bacteremia

When in the bloodstream, the common meningitis-causing organisms (*S. pneumoniae*, *H. influenzae*, *N. meningitidis*, *E. coli* K1, and group B streptococcus) are capable of evading host defense mechanisms,[198,199,292] which involves capsular polysaccharides and other bacterial factors, resulting in a high level of bacteremia (Table 31-4).

Several studies of humans and experimental animals suggest a relationship between the magnitude of bacteremia and development of meningitis due to *E. coli*, group B streptococcus, *H. influenzae* type b, and *S. pneumoniae*.[198,199] For example, a significantly higher incidence of *E. coli* meningitis was noted in neonates who had bacterial counts in blood greater than 10^3 colony-forming units (CFU)/mL (6 of 11, 55%) compared with those with bacterial counts less than 10^3 CFU/mL (1 of 19, 5%). Similarly, meningitis due to *S. pneumoniae* was observed more frequently in patients whose bacterial counts in blood were greater than 1×10^2 to 5×10^2 CFU/mL (6 of 7, 86%) than in those with less bacterial counts in blood (2 of 50, 4%). For *H. influenzae* type b, the level of bacteremia is around 10^2 CFU/mL of blood. Consistent with these clinical findings, a high degree of bacteremia was a primary determinant for meningeal invasion of experimental hematogenous meningitis caused by *E. coli*, group B streptococcus, *H. influenzae* type b, and *S. pneumoniae*.[198,199] All patients with *N. meningitidis* detected in their CSF had *N. meningitidis* detected in their blood, thus also suggesting a relationship between bacteremia and development of meningitis caused by *N. meningitidis*.[87]

TABLE 31-4 **Microbial Factors Contributing to a High Level of Bacteremia**

Pathogens	Bacterial Factors
E. coli	Capsular polysaccharides, O-LPS, type 1 fimbriae, NlpI
Group B streptococcus	Capsular polysaccharides, C5a peptidase? SodA
S. pneumoniae	Capsular polysaccharides, pneumolysin
N. meningitidis	Capsular polysaccharides, LOS, factor-H binding protein, PorA

LOS, lipo-oligosaccharides; LPS, lipopolysaccharides; NlpI, new lipoprotein I; SodA, superoxide dismutase.

Bacterial Traversal of the Blood-Brain Barrier

The bacteria in the bloodstream subsequently traverse the blood-brain barrier, most likely at the cerebral capillaries (*S. pneumoniae*, *N. meningitidis*, *E. coli* K1, and group B streptococcus) and choroid plexus (*H. influenzae*).[198,199,201] Meningitis-causing bacteria cross the blood-brain barrier transcellularly, paracellularly, and/or by means of infected phagocytes (the so-called Trojan horse mechanism).[198,199] Transcellular traversal of the blood-brain barrier has been demonstrated for most meningitis-causing bacteria in infants and children, including group B streptococcus, *E. coli*, and *S. pneumoniae*, whereas *N. meningitidis* has been shown to utilize both transcellular and paracellular mechanisms for traversal of the blood-brain barrier.[29,83,198,199]

Recent studies, however, have shown that a high degree of bacteremia is necessary, but not sufficient, for the development of meningitis and that bacterial binding to and invasion of the blood-brain barrier is a prerequisite for penetration into the brain.[198,199] This concept was well demonstrated with *E. coli* K1, when mutants deleted of the *E. coli* factors contributing to binding to and invasion of the blood-brain barrier were significantly less able to traverse the blood-brain barrier than the parent strain despite causing similar levels of bacteremia.[198,199]

Bacterial traversal of the blood-brain barrier requires specific bacterial factors and their interactions with host receptors (Table 31-5),[198,199] although the complete information on microbial-host factors contributing to penetration of the blood-brain barrier is currently lacking for most meningitis-causing bacteria.

Recent studies have also shown that meningitis-causing bacteria exploit host cell signaling molecules for host cell actin cytoskeleton rearrangements and bacterial invasion of the blood-brain barrier (see Table 31-5).[198,199] *E. coli* invasion of the blood-brain barrier involves focal adhesion kinase (FAK), paxillin, phosphatidylinositol 3-kinase (PI3-K), Src kinase, Rho guanosine triphosphates, signal transducers and activators of transcription (STAT)3, cytosolic phospholipase $A_2\alpha$, ($cPLA_2\alpha$), 5-lipoxygenase, cyteinyl leukotrienes, and protein kinase C, whereas group B streptococcus invasion of the blood-brain barrier is independent of Src activation and *L. monocytogenes* invasion of the blood-brain barrier is independent of FAK and $cPLA_2\alpha$.[198] *N. meningitidis* has been shown to invade the blood-brain barrier involving type IV pili, PilC, NadA, Opa, and Opc proteins.[54,198] The detailed information on how meningitis-causing bacteria exploit host signaling molecules for invasion of the blood-brain barrier, however, remains incompletely understood. For example, the invasion of the blood-brain barrier by unencapsulated meningococcus is mediated by Opc

TABLE 31-5 **Microbial-Host Factors Contributing to Penetration of the Blood-Brain Barrier by Common Meningitis-Causing Bacteria**

Pathogens	Bacterial Factors	Host Receptors	Host Signaling Molecules
E. coli	Type 1 fimbriae, OmpA, flagella, NlpI, IbeA, IbeB, IbeC, CNF1, AslA	CD48, gp96, 37LRP, VEGFR1	FAK, paxillin, PI3-K, Src kinase, Rho GTPases, $cPLA_2\alpha$, 5-lipoxygenase, cyteinyl leukotrienes, STAT3, PKCα
Group B streptococcus	Lmb, FbsA, IagA, HvgA, PilA, LTA, β-hemolysin, ScpB, αC protein	Integrin, GAGs	FAK, Rho GTPases, $cPLA_2\alpha$, 5-lipoxygenase, and cyteinyl leukotrienes
L. monocytogenes	InlB	gC1qR, Met, gp96	PI3-K
S. pneumoniae	Phosphorylcholine, PspC (CbpA), pneumolysin, NanA	PAF receptor, 37LRP	β-arrestin, MAPK
N. meningitidis	Type IV pili, PilC, Opa, Opc, NadA	CD46, CD66, integrin, 37LRP, β_2-adrenoreceptor	JNK1 and 2, β-arrestin

37LRP, 37 laminin receptor precursor; *AslA,* arylsulfatase-like gene; *CNF1,* cytotoxic necrotizing factor 1; *$cPLA_2\alpha$,* cytosolic phospholipase $A_2\alpha$; *FAK,* focal adhesion kinase; *FbsA,* fibrinogen-binding protein A; *GAGs,* glycol aminoglycans; *gC1qR,* globular head of complement component C1q; *HvgA,* hypervirulent group B streptococcus adhesin; *IagA,* invasion-associated gene A; *Ibe,* invasion of brain endothelial cell; *InlB,* internalin B; *JNK,* c-Jun kinase; *Lmb,* laminin-binding protein; *LTA,* lipoteichoic acid; *MAPK,* mitogen-activated protein kinase; *Met,* Met tyrosine kinase; *NadA,* neisserial adhesin A; *NanA,* neuraminidase A; *NlpI,* new lipoprotein I; *OmpA,* outer membrane protein A; *PI-3K,* phosphatidylinositol-3 kinase; *PilA,* pilus protein A; *PKCα,* protein kinase Cα; *PspC,* pneumococcal surface protein C; *ScpB,* C5a peptidase; *STAT3,* signal transducers and activators of transcription; *VEGFR1,* vascular endothelial growth factor receptor 1.

binding to fibronectin, which anchors the bacteria to the integrin receptor on the blood-brain barrier. However, in the bloodstream, *N. meningitidis* is encapsulated and the in vivo relevance of Opc-fibronectin–mediated binding to integrin requires clarification[199,341,365]; and type IV pili have been shown to contribute to paracellular penetration of *N. meningitidis* across the blood-brain barrier.[83] *S. pneumoniae* has been shown to invade the blood-brain barrier via complex interaction of CbpA protein and PAF on activated endothelial cells.[54,199,210]

The mechanisms involved in entry of meningitis-causing bacteria into the blood-brain barrier differ from those involved in the inflammation occurring in response to those bacteria. This concept has been demonstrated for *E. coli*, group B streptococcus, and *N. meningitidis*.[29,143,199,341,365] *N. meningitidis* invasion of the blood-brain barrier involves c-Jun kinases 1 and 2 (JNK1 and JNK2), but the release of interleukin (IL)-6 and IL-8 from the blood-brain barrier involves the p38-mitogen–activated protein kinase (MAPK) pathways.[341]

Blood-Brain Barrier Dysfunction and Intracranial Inflammation

Once bacteria enter the CSF, because of insufficient opsonic and phagocytic activity in the CSF, organisms multiply rapidly, liberating bacterial cell wall or membrane components (lipopolysaccharide, lipoteichoic acid, peptidoglycan, lipoproteins, bacterial toxins), and induce release of inflammatory mediators and toxic compounds, which leads to CSF pleocytosis and increased blood-brain barrier permeability, the hallmarks of bacterial meningitis. However, pleocytosis and increased blood-brain barrier permeability can develop independently of each other in some patients with bacterial meningitis[198,199] (see later).

Complement and opsonic proteins either are found at very low concentrations or are absent entirely within normal CSF,[331] and the CSF is devoid of the factors required for enhancing bacterial killing. When bacteria first invade the meninges, the lack of complement and opsonic proteins within the sanctuary of the CNS may permit the bacteria to multiply unrestrained for some time.[38,111,154,396]

The specific pathophysiologic changes in bacterial meningitis are the result of the bacterial products and the inflammatory response of the host to those products (Fig. 31-3). Initial bactericidal antibiotic therapy results in a rapid release of bacterial products, such as lipopolysaccharides (endotoxins), teichoic acid, and peptidoglycans. For gram-positive bacterial meningitis, lipoteichoic acid and peptidoglycans are the bacterial surface elements that induce inflammation.[198,363] The threshold concentration that triggers inflammation is approximately 10^5 bacterial cell equivalents of cell wall pieces.[355] For gram-negative meningitis, lipopolysaccharides (endotoxins) are the major inflammatory components, with peptidoglycan serving as an important cofactor.[56] The inflammatory threshold is approximately 2 pg of endotoxin, or approximately 10^5 bacterial cell equivalents.[389]

Immune activation in the CNS is initiated by the recognition of different bacterial pathogen-associated molecular patterns (PAMPs). Major pattern recognition receptors (PRRs) involved in initial sensing of bacteria in the CNS include Toll-like receptors (TLRs) 2, 4, 5, and 9 and Nod-like receptors (NLRs), which are involved in triggering an intracellular signaling pathway that leads to activation of transcription factors such as nuclear factor-kB (NF-κB) and the subsequent gene transcription of proinflammatory cytokines and chemokines such as tumor necrosis factor-α (TNF-α), IL-1, and IL-8.[54]

Cytokines and chemokines seem to be the primary drivers of the inflammatory response. The following

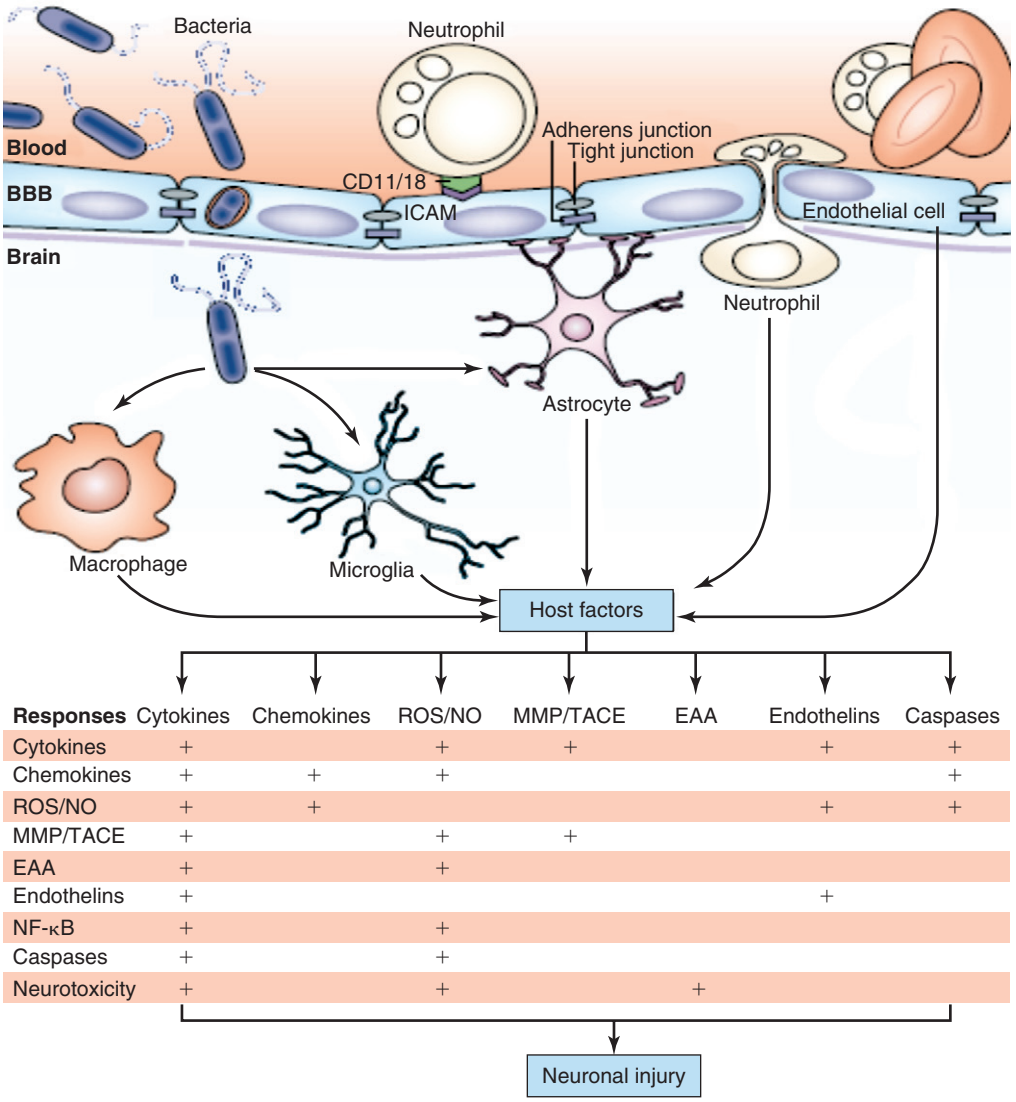

FIGURE 31-3 ■ Host response during bacterial meningitis contributing to neuronal injury. Bacterial entry into the central nervous system elicits the release of many factors from host cells (macrophage, microglia, astrocyte, ependymal cell, endothelial cell, infiltrating inflammatory cell), which along with cytoxicity of bacterial compounds exacerbate host cellular responses, resulting in neuronal injury. + denotes upregulation of specific host factors. BBB, blood-brain barrier; EAA, excitatory amino acids; ICAM, intercellular adhesion molecule; MMP, matrix metalloproteases; NO, nitric oxide; ROS, reactive oxygen species; TACE, tumor necrosis factor-α (TNF-α)–converting enzyme. (See companion website on Expert Consult for a color version of this figure.) (Modified from Kim KS. Pathogenesis of bacterial meningitis: from bacteremia to neuronal injury. *Nat Rev Neurosc* 2003;**4**:376–85.)

cytokines and chemokines are involved in the inflammatory response noted in bacterial meningitis: IL-1, IL-3, IL-4, IL-6, IL-8, IL-10, IL-12, IL-18, interferon-γ, macrophage inflammatory protein, transforming growth factor-β, and TNF-α.[98,135,198,370,398]

TNF-α and IL-1β seem to be key mediators in initiation of meningeal inflammation. Both proteins stimulate vascular endothelial cells to induce adhesion and passage of leukocytes into the CNS and trigger inflammatory processes. Astrocytes and microglia are capable of producing TNF-α.[222,359] TNF-α concentrations are elevated (1) in CSF but not in serum; (2) in animal models of bacterial meningitis; and (3) in patients with bacterial meningitis caused by *H. influenzae*, *N. meningitidis*, *S. pneumoniae*, and *Streptococcus agalactiae*,[198,260] but not in patients with culture-proven viral meningitis.[294] TNF-α levels can be correlated with meningeal inflammation and severity of disease, but lack of TNF-α in the animal model is associated with increased mortality and stronger deficits in spatial memory.[148]

IL-1β can be detected in infants and children with bacterial meningitis, and its presence is correlated significantly with CSF inflammatory abnormalities, TNF-α concentrations, and adverse outcome.[260] The role of IL-1β in bacterial meningitis, however, is inconsistent. Levels of IL-1β were not associated with the degree of the blood-brain barrier disruption in patients with bacterial meningitis.[198]

The chemokines are a superfamily of small chemoattractant cytokines that play an important role in the initiation and modulation of inflammation in bacterial meningitis.[344] IL-8 is one of the well-characterized

chemokines in bacterial meningitis and was found to be chemotactic for neutrophils in the CSF of patients with bacterial meningitis.[143,363]

Complement factors are upregulated in bacterial meningitis. The activated complement cascade in CSF, acting on upregulated complement receptors on brain cells, potentially mediates direct brain damage.[51] Complement factors also are chemoattractants that enhance CSF leukocytosis and indirectly produce brain damage in patients with bacterial meningitis.[110]

Intracisternal administration of antibodies to TNF-α and IL-1β decreased pleocytosis and blood-brain barrier permeability in response to intracisternal injection of *H. influenzae* and *S. pneumoniae*, and blockade of pleocytosis was beneficial in reducing blood-brain barrier permeability in experimental meningitis induced by intracisternal inoculation of *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*.[198] In contrast, intracisternal inoculation of *H. influenzae* and *S. pneumoniae* resulted in increased blood-brain barrier permeability in both normal and leukopenic animals, indicating that increased blood-brain barrier permeability in bacterial meningitis can occur in the absence of pleocytosis.[201] However, no change in blood-brain barrier permeability and absence of pleocytosis after bacterial entry into the CNS usually reflects an early stage of bacterial meningitis.

Neuronal Injury

Neuronal damage is caused by vasculitis; focal ischemia; increased intracranial pressure; cytotoxic, vasogenic, and interstitial edema; transmigrating leukocytes; stimulation of glial cells and astrocytes; cortical necrosis and hippocampal neuronal loss stemming from an inflammatory response to bacteria or bacterial products (bacterial cell wall, teichoid and lipoteichoid acids, lipopolysaccharides, lipoproteins, bacterial DNA); and direct effects of bacterial toxins in the CNS. The various host factors contributing to neuronal injury are shown in Figure 31-3.

Reactive oxygen species (superoxide and hydrogen peroxide) are secreted by TNF-α–stimulated macrophages, including brain microglia, and leukocytes.[198,210] Hydrogen peroxide induces extensive neuronal damage.[198,210] Nitric oxide also can be induced in brain cells in response to bacterial products.[203] Nitric oxide and superoxide radicals react to form peroxynitrite anion, which decomposes and forms nitrogen dioxide, hydroxyl radicals, and strong oxidant compounds.[33] Peroxynitrite seems to be an important neuronal toxin.[209] Neuronal damage caused by reactive oxygen species and reactive nitrate species occurs via at least two separate pathways—via lipid peroxidation and subsequent cell membrane instability and via DNA fragmentation and subsequent activation of poly(adenosine diphosphate ribose) polymerase (PARP) and cellular energy depletion.[198,210] Reactive oxygen species also activate NF-κB, a transcription factor affecting genes such as cytokines and chemokines, and peroxynitrite initiates activation of caspases.[210]

In addition, macrophages secrete excitatory amino acids, such as glutamate, which potentially kill *N*-methyl-D-aspartate receptor–positive cells[201] and glutamate concentrations in the CSF are shown to be increased in patients with bacterial meningitis.[198]

Meningitis causes damage in the cortex and the hippocampal region via different mechanisms.[198] Cortical damage is mainly via cellular necrosis surrounded by an area of caspase-3–dependent apoptosis. Damage in the hippocampus is mediated not only via the classic caspase-3–dependent pathway but also by caspase-independent apoptosis mediated by apoptosis-initiating factor.[37,39,248]

The increasing concentrations of chemotactic factors in the subarachnoid space lead to accumulation of large numbers of neutrophils in the CSF, but the growth of bacteria is not slowed significantly by this response.[110] Impaired phagocytosis by neutrophils in the meningeal spaces may be related to weak activity in fluid medium, lack of complement activity and opsonization, and poor penetration of IgM and IgG through the blood-brain barrier, even during acute *H. influenzae* and *S. pneumoniae* meningitis.[155] The contribution of leukocyte entry into the CSF to bacterial meningitis remains inconsistent. Blockage of leukocyte entry into the CSF was associated with poorer prognosis (likely secondary to an increase in bacterial counts in the blood) but did not affect the risk for brain damage,[50] whereas inhibition of leukocyte migration or of products released by leukocytes is shown to interfere with the pathogenesis of bacterial meningitis.[198]

Bacterial cell wall fragments, endotoxin, or both also contribute to vascular permeability. In experimental *E. coli* meningitis, the CSF endotoxin concentration increased markedly after treatment with β-lactam antibiotics. This increase was associated with an increase in brain water content. This effect could be blocked by polymyxin or a monoclonal antibody, both of which inactivate endotoxin.[198]

The inflammatory and vascular events described earlier act synergistically to produce the clinical symptoms and long-term sequelae that are noted in patients with bacterial meningitis. Altered vascular permeability leads to vasogenic edema, inflammatory and electrolyte changes lead to cytotoxic edema, and alterations in production and absorption of CSF lead to interstitial edema. The cytokines also trigger increased cerebral blood flow and further formation of edema, resulting in increased intracranial pressure.[18,198] The increased intracranial pressure and vasculitis lead to a subsequent decrease in cerebral blood flow, and maintenance of an appropriate cerebral perfusion pressure is crucial to maintaining cerebral blood flow.[18,198] Activation of the coagulation cascade predisposes the patient to venous, microvascular, and, rarely, arterial thrombosis. Direct neurotoxic damage by inflammatory cells also may contribute to the neuropathologic changes seen in bacterial meningitis.[198,210]

Studies in experimental animals and human autopsy cases of bacterial meningitis reveal that neuronal injury occurs mostly as apoptosis in the dentate gyrus of the hippocampus formation and as necrosis in the neocortex and the CA1-4 region of the hippocampus.[149,198] In other regions of the brain, neurons die with necrotic morphology.[149] Not only cellular destruction but also proliferation of neuronal progenitor cells has been observed in patients after bacterial meningitis.[151] Increased neural progenitor

cell proliferation and differentiation were also observed after experimental bacterial meningitis.[147] These findings suggest an endogenous potential of cell renewal in the hippocampal formation in bacterial meningitis. It remains to be determined whether stimulation of endogenous neurogenesis can be used as a potential option in survivors of meningitis.

In the adult brain, neural progenitor cells maintain the ability to proliferate and differentiate into new neurons. The progenitor cells are located predominantly in the subgranular zone of the dentate gyrus and the subventricular zone of the lateral ventricle. In the subgranular zone, the stem cells proliferate and differentiate into progenitor cells. The newly formed cells subsequently migrate into the granular layer of the dentate gyrus, differentiate into mature, functional neurons, and become integrated into the hippocampal network. The hippocampus is therefore potentially equipped for repair. However, because neurofunctional sequelae of bacterial meningitis related to hippocampus function persist throughout childhood and adulthood, the capacity of self-repair seems insufficient to compensate for the brain damage. It remains to be determined whether the regenerative capacity of the hippocampus is compromised by bacterial meningitis.

Factors Predisposing the Host to Bacterial Meningitis

Factors that predispose the host to the development of bacterial infection in other sites also predispose the host to the development of bacterial infection of the CNS. A strong interrelationship exists among factors relating to the host, the organism, and the environment with regard to the pathogenesis and outcome of meningitis. Although presented separately, they must be considered a complex interplay of factors that leads to infection.

An increased incidence of bacterial meningitis is observed in the very young; boys are affected more frequently than girls, and the severity of disease also is increased in these groups. A neonate is predisposed to development of septicemia and meningitis by factors that reflect physiologic deficiencies or immaturity of host defense mechanisms, including (1) decreased phagocytic and bactericidal activity of polymorphonuclear leukocytes, (2) defects in the response of neonatal leukocytes to chemotactic factors, (3) a deficiency in the capacity of leukocytes to support opsonization, and (4) defects in microtubular length and number that decrease the motility of the neonatal leukocytes compared with leukocytes from older children. Deficiencies in serum complement components (C1q, C3, and C5), low levels of serum properdin, and low concentrations of serum IgM and IgA have been documented. Despite transplacental acquisition of IgG, antibodies against specific infective agents may be lacking.[200] The precise age at which each of these factors reaches the concentration and functional activity noted in older children and adults is unclear and undoubtedly varies from individual to individual. In part, meningitis in children aged 1 month to 1 year may reflect qualitative or quantitative differences of the inflammatory and immunologic responses compared with older children.

The increased risk for development of meningitis in the normal host with less than completely mature immunologic and inflammatory responses to infection may be attributable to age alone. This factor is exemplified in the report,[77] where the risk for recurrent bacteremia was studied in young children. Within 18 months of having bacteremic illness, none of 42 children older than 24 months of age had a documented additional episode of bacteremia or systemic infection. Fifteen of 135 children (11%) younger than age 24 months at the time of the initial bacteremic disease had at least one additional documented bacteremic illness, however. Of these 15 children, 14 contracted both infections before reaching 2 years of age. Seven of these 15 children had meningitis. Only 2 patients had documented congenital or hereditary disorders of immunoglobulin or complement concentration or function.

There is increasing evidence that genetic polymorphisms in the inflammatory response, complement system, coagulation, and fibrinolysis pathways influence the genetic predisposition and outcome in bacterial meningitis.[54] A genetic determination for the predilection of some normal children for the development of bacteremia and meningitis has been suggested.[54,357] The ability of the host to produce, within the CSF, IL-12 and TNF-α–induced interferon-γ is important in the natural immunity to various microorganisms that may cause meningitis.[54,214]

Deficiencies and polymorphisms in the PRRs downstream signaling cascade have been associated with invasive pneumococcal meningitis.[285] IL-1 receptor–associated kinase 4 (IRAK-4) is an intracellular kinase that is involved in signal transduction in the TLR pathways, and MyD88 is a general adaptor molecule for TLR signaling. Individuals with IRAK-4 and MyD88 deficiency are at a high risk for developing pneumococcal meningitis, with increasing mortality.[283,284,374] IRAK-4 and MyD88, however, appear to be important at a young age, because no fatal disease after 8 years of age and no invasive bacterial infection after 14 years of age have been reported.[374]

Congenital or acquired abnormalities of the immune system may predispose the host to the acquisition of bacterial infections. Congenital deficiency of the three major immunoglobulin classes may predispose the host to the acquisition of severe bacterial infection. Congenital defects of thymic-dependent, small lymphocyte function or combined T- and B-cell defects are detrimental to host defense. A deficiency of $CD4^+$ helper-inducer T cells in patients with bacterial meningitis has been reported and may contribute to the impaired antibody synthesis to bacterial capsular polysaccharides in this disease.[296] Multiple studies have shown that deficiencies of various components of the complement system and increased consumption or loss of complement have been associated with increased risk for development of bacterial meningitis caused by encapsulated organisms.[54]

An increased incidence of overwhelming infection, including meningitis, occurs after splenectomy, but the likelihood of development of such infection depends on

the age of the child at the time of splenectomy, the time since splenectomy, and the original indication for splenectomy.[109] Congenital asplenia or polysplenia also has been associated with an increased incidence of septicemia and meningitis caused by *S. pneumoniae*,[109] *H. influenzae* type b, and gram-negative enteric microorganisms. Children with sickle-cell disease and other hemoglobinopathies have meningitis caused by *S. pneumoniae*, *H. influenzae*, and *Salmonella* spp. more frequently than do normal children.

Children with malignant neoplasms with or without neutropenia seem to be susceptible to development of meningitis caused by organisms of low virulence that pose a minimal threat to healthy children, presumably because of abnormalities in immunologic function.[342] Decreased production of normal immunoglobulins, delayed and defective antibody responses to antigenic stimuli, production of abnormal immunoglobulins, depression in the clearance mechanisms of the reticuloendothelial system, and depression of cellular immunity have been documented in children with malignant neoplasms involving the reticuloendothelial system. In addition, the use of irradiation or immunosuppressive agents and antimetabolites predisposes the host to the development of infection in the CNS. Attributing the occurrence of bacterial meningitis in this population directly to these agents rather than to the disease for which this therapy has been provided may be difficult. Meningitis occurring after neurosurgical manipulation for tumors of the CNS in non-neutropenic children usually develops within 1 month of the neurosurgery.[342]

Malnutrition also predisposes children and adults to infectious disease. Impaired cellular immune responses, low levels of serum complement, impaired phagocytic activity of neutrophils, and decreased serum concentrations of transferrin have been documented in malnourished children.[117]

Patients with systemic diseases, such as diabetes mellitus, renal insufficiency, adrenal insufficiency, cystic fibrosis, hypoparathyroidism, and exudative enteropathy, have an increased frequency and severity of CNS infections.[45] Children with diabetes mellitus, coma caused by drug overdose, and Cushing syndrome have been shown to be at increased risk for development of bacteremia or meningitis caused by *H. influenzae* type b.[227] Some type of underlying condition was noted for 21 percent (37 of 181) of the children with pneumococcal meningitis in a multicenter study.[16] The most common of these conditions was some disorder of the CNS, which occurred in 16 children (9%). Defective chemotaxis, phagocytosis, and bactericidal function accompany these disorders and may explain in part the increased susceptibility of these individuals to infection.[117,118]

In the normal host, bacterial infections at sites other than the leptomeninges are associated with an increased incidence of CNS infection. Infection may spread hematogenously to the meninges in children with endocarditis, pneumonia, or thrombophlebitis or by direct extension from sinusitis, mastoiditis, or osteomyelitis of the skull.[198]

An increased risk for development of pneumococcal meningitis also occurs in children after placement of cochlear implants. The incidence of meningitis caused by *S. pneumoniae* in patients after receiving cochlear implants was 138.2 cases per 100,000 person-years, which represents a more than 30-fold increase over the age-controlled general population.[297] From 1999 to 2002, some children were implanted with cochlear devices, including a positioner, which were subsequently removed from the market as a result of an associated marked increase in incidence of pneumococcal meningitis. After removing the influence of cochlear devices containing a positioner, the incidence of pneumococcal meningitis among children with cochlear implants was still 16 times higher than that of an age-matched control population.

PATHOLOGY

The most detailed account in English of the pathologic changes occurring with meningitis was written in 1948 by Adams and colleagues.[4] They described the meningeal, cerebral, and vascular changes found post mortem in 14 patients who died of *H. influenzae* infection 14 hours to 76 days after the onset of disease. Although most patients in their series received inadequate treatment (effective antibiotic therapy was unavailable), the pathologic findings they describe differ little from the findings of subsequent reports for patients who died despite administration of antibiotics.[102,301,337]

Meningeal exudates of variable thickness may be found (Fig. 31-4). Purulent material is distributed widely but may accumulate around the veins and venous sinuses, over the convexity of the brain, in the depths of the sulci, in the sylvian fissures, within the basal cisterns, and around the cerebellum. The spinal cord may be encased in pus. Ventriculitis (purulent material within the ventricles) has been noted in children who died of their diseases. Subsequent experience suggests that ventriculitis may be a common finding in children with bacterial meningitis who survive, particularly neonates. Invasion of the ventricular wall with perivascular collections of purulent material has been noted. Loss of ependymal

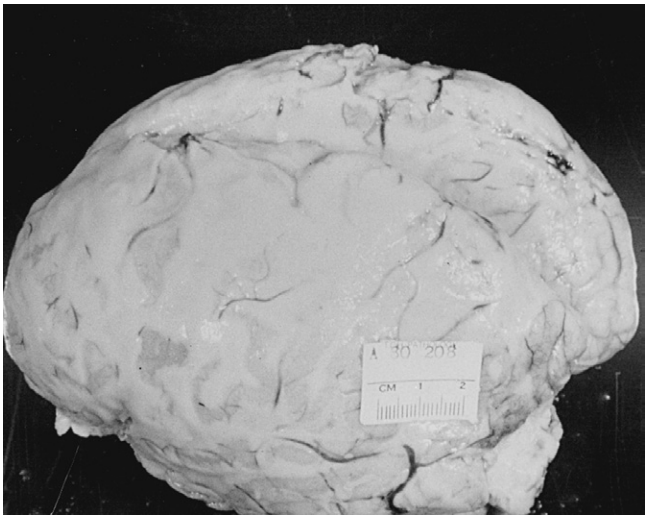

FIGURE 31-4 ■ Note extensive purulent exudates over entire cerebral cortex in a patient who died as a result of bacterial meningitis.

lining and subependymal gliosis may be seen. In some studies, purulent exudates tended to be thicker over the convexity of the brain in patients with pneumococcal meningitis than in patients with other forms of meningitis.[102,301]

Vascular and parenchymatous changes have been shown at necropsy. Polymorphonuclear infiltrates extending to the subintimal region of small arteries and veins have been associated with the exudative meningeal process. Thrombosis of small cortical veins associated with necrosis of the cerebral cortex may be noted. Occlusion of one of the major venous sinuses, subarachnoid hemorrhage secondary to necrotizing arteritis, and necrosis of the cerebral cortex in the absence of identifiable thrombosis of small vessels rarely may be observed. Reactive microglia and astrocytes may be identified in the cerebral cortex, particularly subadjacent to regions of heavy subarachnoid exudate. Because no bacteria are found in the cerebral cortex, these pathologic changes should be viewed as a noninfectious encephalopathy. "Toxic or circulatory factors" were suggested as possible causes by Adams and associates.[5] Dodge and Swartz[102] suggested systemic hypoxia and fever as additional possible causes. They also noted that an increase in intracranial pressure might interfere with cerebral circulation.

Impaired consciousness, deficits in motor and sensory functions, seizures, and retardation may be observed. Damage to the cerebral cortex, reflecting the effects of vascular occlusion, hypoxia, toxic encephalopathy, bacterial factors, inflammatory mediators, small molecule effectors, or some combination of these factors, provides an adequate explanation for these observations.

Hydrocephalus that develops in patients beyond the newborn period is an uncommon complication of meningitis. Most often, hydrocephalus is communicating and is the result of adhesive thickening of the arachnoid around the cisterns at the base of the brain. Less frequently, the aqueduct of Sylvius or the foramina of Magendie and Luschka are obstructed by fibrosis and reactive gliosis. The ensuing ventricular dilation may be coupled with coexistent necrosis of nervous tissue because of the meningitis itself or because of occlusion of cerebral veins and, rarely, arteries.

Subdural effusions occur frequently during the course of meningitis. The exact pathogenesis is unknown. The high incidence of effusion and the fact that subdural fluid collections may be found early in the course of bacterial meningitis in children suggest, however, that subdural effusions should be considered a concomitant occurrence with meningeal inflammation rather than a complication of the disease. Numerous veins traverse the subdural space, and inflammation of these veins and of the dural capillaries could produce an increase in vascular permeability and loss of albumin-rich fluid into the subdural space. The ratio of albumin to gamma globulin is higher in the subdural fluid of children with meningitis than in serum.[160] When the inflammatory process subsides, formation of fluid generally ceases, but its presence may persist because of a continued transudation through newly formed vessels in the subdural membrane. Subdural empyema, as opposed to subdural effusion, occurs rarely.[5,102,337]

Many factors contribute to the increase in intracranial pressure in patients with meningitis. Endotoxin and fragments of the cell wall of gram-positive organisms are capable of inducing the release of IL-1β and TNF-α from macrophages and other sources.[198,354] These substances, in addition to other interleukins and metabolites, affect endothelial cells, affecting the function of the vasculature and its interaction with neutrophils and other inflammatory cells. They also play an important role in the pathogenesis of increased intracranial pressure and cerebral edema in patients with meningitis by altering cerebral blood flow, intracranial blood volume, and permeability of the cerebral vasculature.[268] Experimentally, the main components of the blood-brain barrier—endothelial cells, astrocyte-end feet, and pericytes—have been found to be sensitive to the effects of such inflammatory mediators.[27] Intercellular junctions, which normally are tight, are open in experimental meningitis, which is associated with an increased permeability to circulating albumin.[291] Pinocytotic vesicles also are noted within the cytoplasm of endothelial cells. Swelling of cellular elements (cytotoxic edema) also has been noted.

Alterations in CSF resorption exacerbate cerebral edema and increase intracranial pressure further. In experimental meningitis, resorption of CSF is diminished because an accumulation of proteins, leukocytes, and other materials interferes with the function of the arachnoid villus.[318]

During the course of meningitis, excess secretion of antidiuretic hormone (ADH) occurs, which induces water retention and exacerbates electrolyte abnormalities already created secondary to the inflammatory process occurring in the CNS. Cellular electrolyte disturbances may depolarize neuronal membranes, predisposing the host to seizure activity. Increased oxidation of glucose, increased lactate production, and depletion of high-energy compounds such as adenosine 5′-triphosphate and phosphocreatine are observed. Hypoglycorrhachia results primarily from decreased transport of glucose across the inflamed blood-brain barrier and from increased use of glucose by host tissues. Use of glucose by bacteria and polymorphonuclear leukocytes is of less relative importance.[102,373]

CLINICAL MANIFESTATIONS AND PATHOPHYSIOLOGIC RELATIONSHIPS

The clinical features of bacterial meningitis in infants and children can be subtle, variable, and nonspecific, or even absent.[200] In infants, they might include fever, hypothermia, lethargy, irritability, poor feeding, vomiting, diarrhea, respiratory distress, seizures, or bulging fontanelles. In older children, clinical features might include fever, headaches, photophobia, nausea, vomiting, confusion, lethargy, or irritability. Signs of meningeal irritation are present in 75 percent of children with bacterial meningitis at the time of presentation.[229] In contrast, a retrospective review of 326 children presenting to a pediatric emergency department in the Netherlands between 1988 and 1998 with meningeal irritation revealed that 30 percent had bacterial meningitis.[275] Absence of meningeal

irritation in children with bacterial meningitis was substantially more common in those younger than age 12 months (Table 31-6).[200]

Inflammation of the meninges generally is associated with nausea, vomiting, irritability, anorexia, headache, confusion, back pain, and nuchal rigidity. In many cases, Kernig and Brudzinski signs are noted. The Kernig sign is present when the leg is flexed 90 degrees at the hips and cannot be extended more than 135 degrees. The Brudzinski sign is present if the thighs and legs are flexed involuntarily when the neck is flexed. All of these findings suggest irritation of inflamed sensory nerves, which produces a reflex contraction of certain muscles in an attempt to minimize pain. These findings also can be the result of increased intracranial pressure and an associated distortion of nerve roots. These signs can be accompanied by hyperesthesia and photophobia. Currently, no satisfactory pathophysiologic explanation for photophobia exists.

Signs of meningeal inflammation may be minimal in the infant, but irritability, restlessness, and poor feeding may be noted. Nuchal rigidity and Kernig and Brudzinski signs may occur late in a young child. Nuchal rigidity may not be elicited in comatose patients or when signs of focal or diffuse neurologic impairment are present. At the time of initial evaluation, 60 to 80 percent of children have a stiff neck.[199] A review of 1064 cases of bacterial meningitis in children beyond the neonatal period revealed that 16 (1.5%) had no meningeal signs during their entire period of hospitalization, despite the presence of CSF pleocytosis.[145] Fever, a hallmark of infection, generally is present; its absence in a patient with signs of meningeal inflammation, although infrequent, is not unusual.

The relative frequency with which selected findings in infants, children, and adults with bacterial meningitis are summarized in Table 31-6.*

Increased intracranial pressure is the rule; it may be reflected by complaints of headache in older children and by a bulging fontanelle and diastasis of sutures in infants. Papilledema is an uncommon finding in acute meningitis, presumably because of the brief duration of increased pressure at the time of diagnosis. When papilledema is observed, venous sinus occlusion, subdural empyema, or brain abscess should be sought.

A major contributing factor to increased intracranial pressure in bacterial meningitis is the development of cerebral edema. Vasogenic edema occurs as a consequence of increased permeability of the blood-brain barrier. Interstitial edema may occur secondary to decreased clearance of CSF at the arachnoid villi and subsequent obstructive hydrocephalus. Cytotoxic cerebral edema mediated by the release of toxic factors from neutrophils and bacteria leads to increased concentration of intracellular water and sodium and loss of intracellular potassium. In many cases,[114] meningitis is associated with the release of ADH, causing water retention and a relative dumping of sodium by the kidney. If the patient is given excessive free water during therapy, a further increase in intracranial pressure may be noted.

Transient or permanent paralysis of cranial nerves may be noted. Deafness or disturbances in vestibular function are common findings; optic nerve involvement with blindness rarely occurs. Involvement of the eighth cranial nerve may reflect disease at the level of the cochlear and vestibular end organs, which may be related to concomitant infection of the inner ear. Paralysis of extraocular and facial nerves may be noted. Torticollis has been reported in two children with partially treated meningitis.[242] Obtundation, stupor, coma, and focal neurologic signs may be seen in children with bacterial meningitis.

Table 31-7 shows data for 235 children with bacterial meningitis in a prospective study analyzed according to the type of organism responsible for meningitis. Overall, 14.9 percent of children were semicomatose or comatose at the time of admission; rates for children with pneumococcal or meningococcal meningitis were higher than rates for children with *H. influenzae* disease. Focal neurologic signs were present at the time of admission in 16.5 percent of the total group (34.3% of children with pneumococcal meningitis). The presence of focal neurologic signs at the time of admission indicated a poor prognosis and could be correlated with persistent abnormal neurologic examinations at 1, 3, and 6 months ($p < .01$) and at 1 year after discharge ($p < .03$). The presence of focal signs at the time of admission also correlated with the presence of retardation ($p < .001$), as determined by detailed psychometric testing after discharge.

Generally, when focal signs are noted in the absence of seizures, cortical necrosis, occlusive vasculitis, or thrombosis of cortical veins has occurred. Thrombosis of meningeal vessels or cortical necrosis may be associated with hemiparesis or quadriparesis and with focal seizures. These signs may appear during the first 3 or 4 days of illness or, less commonly, may be noted after the first or second week of infection. A highly significant association ($p < .001$) between neurologic signs indicative of cerebral injury and late (1 to 15 years after the acute infection) afebrile seizures has been noted.[287] Ataxia has been a presenting sign of meningitis in numerous children and adults.[324] Adolescents with meningitis may present with

TABLE 31-7 **Frequency of Selected Findings in Children with Bacterial Meningitis**

	Total Group	*H. influenzae*	*S. pneumoniae*	*N. meningitidis*
No. patients	235	151	35	26
Level of consciousness (%)				
Irritable or lethargic	184 (78.3)	117 (77.5)	24 (68.6)	21 (80.8)
Somnolent	16 (6.8)	13 (8.6)	1 (2.8)	1 (3.8)
Obtunded-semicomatose	27 (11.5)	15 (9.9)	8 (22.9)	4 (15.4)
Comatose	8 (3.4)	6 (4)	2 (5.7)	0 (0)
Focal neurologic signs on admission (%)	37 (16.5)	22 (14.6)	12 (34.3)	2 (7.7)
Seizures before admission (%)	48 (20.4)	35 (23.2)	8 (23)	3 (11.5)
Seizures in hospital (%)	61 (26)	43 (28)	12 (34)	5 (19)

behavioral abnormalities that may be confused with drug abuse or psychiatric disorders.[26]

Approximately 20 percent of children with bacterial meningitis experience seizures before admissions, and approximately 26 percent have them during the first or second day in the hospital. Green and colleagues[163] retrospectively examined the frequency of seizures before or at the time of presentation in children with meningitis. They found that 111 of 410 (27%) children with bacterial meningitis had seizures at or before the time of diagnosis; 88 of these children had complex seizures (focal, prolonged, or more than one in a 24-hour period). They found that all children with bacterial meningitis who presented with seizures had other signs or symptoms of meningitis, such as altered level of consciousness, nuchal rigidity, or complex seizures and petechial rash. The frequency of seizure activity is similar for children with *H. influenzae* type b or pneumococcal meningitis; seizures occur in children with meningitis caused by these organisms approximately twice as frequently as in children with meningococcal meningitis. In a multicenter study of 181 children with pneumococcal meningitis, 41 (23%) developed seizures before admission; 74 percent of preadmission seizures were generalized.[16]

Overall, seizures are noted in approximately 30 percent of children with bacterial meningitis. Seizures noted before or during the first several days of hospitalization are of no particular prognostic significance. Specifically, their occurrence does not herald the development of a permanent seizure disorder. Seizures that are difficult to control or that persist beyond the fourth hospital day and seizures that occur for the first time late in the hospital course may be of greater significance and have been associated with permanent sequelae of meningitis. Children with focal seizures have a greater likelihood for development of sequelae of meningitis than do children with generalized seizure activity. Focal or prolonged seizures probably indicate serious cerebral vascular disturbances or cerebral infarction. Seizures that occur before admission have correlated positively with abnormal audiometric studies and permanent hearing handicaps. Seven percent of patients with bacterial meningitis have focal or generalized seizures 3 months to 15 years after recovery from bacterial meningitis.[287]

Collections of fluid in the subdural space can be shown in 50 percent of infants and children during acute illness.[102] In a prospective study of infants 1 to 18 months old with bacterial meningitis, subdural effusions were noted in 43 percent of infants with *H. influenzae* meningitis, 30 percent of infants with pneumococcal meningitis, and 22 percent of infants with meningococcal meningitis. Subdural effusions were found in 24 percent (25 of 103) of children undergoing neuroimaging in the multicenter pediatric surveillance study of pneumococcal meningitis.[16,338] No greater incidence of neurologic sequelae or developmental delay was found on long-term follow-up in patients with effusion compared with patients with bacterial meningitis who did not have effusion.[338] Subdural effusions may cause enlargement in head circumference or may be responsible for abnormal transillumination of the skull, and vomiting, seizures, a full fontanelle, focal neurologic signs, or persistent fever sometimes may be noted.

Blindness and optic atrophy may be related to optic arachnoiditis or infarction of the occipital lobe. Spastic paraparesis with sensory loss in the lower extremities may be secondary to meningomyelitis, spinal cord infarction, or both.

Shock may be associated with any form of overwhelming bacteremia, but it occurs most often in patients with fulminant meningococcemia. In a prospective study, 3.8 percent of children with meningococcal meningitis developed profound hypotension. In the same study, shock occurred in 5.5 percent of children with *H. influenzae* meningitis. Endotoxin has been detected by limulus lysate assay in the blood and CSF of children with meningococcal and *H. influenzae* meningitis.[304] Sixteen percent of the children in the multicenter pneumococcal meningitis study were in shock on admission.[16] Signs of disseminated intravascular coagulation may accompany hypotension in these patients.

Facial cellulitis (including buccal and periorbital cellulitis), pneumonia, epiglottitis, endophthalmitis, and other suppurative manifestations can manifest at the time of admission in any patient with bacterial meningitis. In one study of children with buccal cellulitis, less than 10 percent (7 of 73 children) had concomitant bacterial meningitis documented by lumbar puncture as part of their initial evaluation.[24] Five of the 7 children had no clinical evidence of meningeal irritation. *H. influenzae* and *S. pneumoniae* were cultured from 2 patients with periorbital cellulitis, and no clinical evidence of

meningeal irritation or abnormal CSF cell counts or results of chemistries was found.[312] In the largest review of facial cellulitis caused by *S. pneumoniae*,[161] 15 of 52 children had a lumbar puncture performed; 2 (13.3%) had a pleocytosis (18 white blood cells [WBCs]—52% polymorphonuclear leukocytes; and 9 WBCs—91% polymorphonuclear leukocytes). The Gram stain and cultures of the CSF specimens were negative. Lumbar puncture should be considered for children with facial cellulitis who are younger than age 18 months and possibly bacteremic with *S. pneumoniae*.

Arthralgia and myalgia are noted in many patients with bacterial meningitis, reflecting the systemic nature of the disease. Arthritis also may occur and does so most commonly during the course of meningococcal disease; generally, it is transient. Early findings of arthritis may be related to direct invasion of the joint by the meningococcus. Arthritis that develops late in the course of meningococcal or *H. influenzae* meningitis may be an immune complex–mediated event. Petechial or purpuric lesions may be seen in 50 percent of patients with meningococcal meningitis[102] but also may accompany any infectious or noninfectious disease process in which vasculitis occurs. Purpura, shock, and hypothermia indicate a poor prognosis.

Pericardial effusions may be present; they generally resolve during the course of antibiotic therapy. In some cases, pericardial effusions are the cause of persistent fever, and pericardiocentesis or an open drainage procedure may be required.

DIFFERENTIAL DIAGNOSIS

The signs and symptoms described earlier suggest meningeal or intracranial pathologic processes but are not pathognomonic of acute bacterial infection. Tuberculous meningitis, fungal meningitis, aseptic meningitis, brain abscess, intracranial or spinal epidural abscesses, cranial osteomyelitis, subdural empyema, bacterial endocarditis with embolism, ruptured dermoid cysts, ruptured spinal ependymomas, and brain tumors may show similar signs and symptoms. Differentiation of these disorders depends on careful examination of CSF obtained by lumbar puncture and additional immunologic, radiographic, and imaging studies, as delineated later.

Recurrent bacterial meningitis may be the result of a bacterial infection in the setting of an immunocompromised condition or a communication between the nasal passage or ear and the meninges from congenital anatomic defect or the result of trauma. If rhinorrhea or otorrhea is present, a leak may be suspected, but documenting that CSF is present and locating the site of leakage are difficult when the sample is small or contaminated. Sectional (2 mm) coronal cranial CT has been reported to be a noninvasive method for delineating anatomic abnormalities in children with recurrent meningitis.[348]

Meurman and associates[246] showed that an extra band of transferrin is located in the β_2-fraction after protein electrophoresis of CSF. This extra β_2-transferrin band could not be shown in serum, nasal secretions, saliva, tears, or perilymph and endolymph, suggesting that this immunochemical method is useful for documenting that fluid found draining from the nose or ear was CSF. The amount of sample required is small (<50 μL). Differential suction may permit demonstration of the site of the anatomic communication among the nose, the ear, and the meninges. Moderate contamination with other body fluids does not invalidate the method. The method is noninvasive and safe for the patient.

Noninfectious causes of meningitis include medications such as nonsteroidal anti-inflammatory drugs (NSAIDs), trimethoprim-sulfamethoxazole, isoniazid, metronidazole, intravenous immune globulin treatment, Behçet syndrome, systemic lupus erythematosus, mixed connective tissue disease, sarcoidosis, familial Mediterranean fever, Vogt-Koyanagi syndrome, procedures involving the CNS (neurosurgery, spinal anesthesia, intrathecal injection), subarachnoid hemorrhage, vein of Galen aneurysm, Mollaret meningitis, intracranial/intraspinal tumors, and cysts.

DIAGNOSIS

Early diagnosis and treatment of bacterial meningitis are imperative in reducing mortality rates and morbidity. Physicians must perform a lumbar puncture on any child in whom they suspect the diagnosis after a careful history and physical examination have been performed, unless specific contraindications to this procedure (e.g., clinical signs of increased intracranial pressure in a patient with a closed fontanelle and closed sutures, evidence of mass lesions, cardiopulmonary compromise) are present.

Measurement of opening pressure, often neglected in infants and young children, is an important component of each CSF examination. When the pressure is very high, only enough fluid to permit a careful examination should be removed. Compression of the jugular vein should be avoided unless compression of the spinal cord is suspected. The CSF appearance can be cloudy, stemming from high concentrations of bacteria, protein, WBCs and/or red blood cells (RBCs). Xanthochromic CSF derives its color primarily from bilirubin pigment. Hemorrhage, bilirubin staining in icteric patients who have meningitis (i.e., neonates, patients with leptospirosis), or an elevated protein concentration of CSF may be associated with xanthochromia.

CSF should be examined immediately. The total number of WBCs should be counted in a counting chamber; and after cytocentrifugation, a differential cell count should be done on a Wright-stained smear of the sediment. The normal CSF of children age 3 months or older contains less than 6 WBCs/mm^3. Ninety-five percent of children older than age 3 months have no polymorphonuclear leukocytes in the CSF; the presence of a polymorphonuclear leukocyte in the CSF may be regarded as abnormal. When a lumbar puncture has been performed in a febrile child and a single polymorphonuclear leukocyte has been noted, careful clinical observation is imperative, and treatment should be considered until the results of the culture of the CSF are known.

If the lumbar puncture has been traumatic, a total cell count can be done in a counting chamber. The RBCs can be lysed by acetic acid, and a cell count can be repeated. If the total number of WBCs compared with the number of RBCs is greater than that in whole blood, one can assume the presence of CSF pleocytosis. One simple way to estimate the WBC count in the presence of RBCs is to allow 1 WBC per 1000 RBCs/mm^3. However, this adjustment cannot be reliably performed in the presence of clot. CSF protein should be measured (usually elevated in bacterial meningitis), and the CSF glucose concentration should be compared with the blood glucose concentration that has been obtained concomitantly. In patients with bacterial meningitis, depression of CSF glucose and of the ratio of CSF to blood glucose (normally 40% to 60%) is the rule (Table 31-8).

Separate smears should be made, and one smear should be Gram stained for bacteria. A Kinyoun stain for mycobacteria is performed if tuberculous meningitis is suspected. The probability of visualizing bacteria on a Gram stain of CSF depends on the number of organisms present.[41,122] The percentage of positive smears is 25 percent with less than 10^3 CFU/mL, 60 percent in the range of 10^3 to 10^5 CFU/mL, and 97 percent with greater than 10^5 CFU/mL.[217] Gram stain is positive in about 90 percent of children with pneumococcal meningitis, about 80 percent of children with meningococcal meningitis, half of patients with gram-negative bacillary meningitis, and a third of patients with *Listeria* meningitis.[200] Cytospin centrifugation increases the chances of detecting organisms in Gram-stained CSF.[200] A low CSF WBC count with positive Gram stain is a risk factor for an unfavorable outcome.[16,200] Quellung and agglutination reactions can provide immediate identification of various organisms if the appropriate type of specific antisera is available.

Treating a child with bacterial meningitis with an antibiotic before performing initial lumbar puncture usually does not alter markedly the cell counts or chemical results obtained (Table 31-9). Even when children received appropriate antibiotics for meningitis intravenously for 44 to 68 hours, the bacterial character of the chemical and cellular findings could be discerned in most cases.[43] CSF culture, however, can be negative in children who receive antibiotic treatment before CSF examination. Complete sterilization of *N. meningitidis* occurred within 2 hours of giving a parenteral third-generation cephalosporin and the beginning of sterilization of *S. pneumoniae* from CSF by 4 hours into treatment.[188] In such children, pleocytosis and an increased CSF protein concentration are usually sufficient to establish the diagnosis of bacterial meningitis. Blood cultures or nonculture diagnostic tests can help in identifying the infecting organism.

The CSF should be cultured on a blood agar plate and a chocolate agar plate. The CSF specimens always should be cultured, even when the fluid appears to be crystal clear and acellular.

In the 1970s, countercurrent immunoelectrophoresis was shown to be a useful technique for rapid diagnosis (within 1 hour) and management of bacterial meningitis caused by *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis* (groups A, C, W135, and D), and group B streptococcus. It was also used to detect antigens from K1 strains of *E. coli* or *L. monocytogenes*.[120,200,241] The methodology was sensitive and could detect nonviable bacteria, permitting the detection of bacterial antigen, even in patients who have been pretreated with appropriate antibiotics. If this technique is employed, it is imperative to use antisera that have the greatest possible sensitivity and specificity, although it is rarely available currently.[182,326] A negative result of countercurrent immunoelectrophoresis does not exclude the diagnosis of bacterial meningitis.

Latex particle agglutination commercial kits are available for detecting the polysaccharide antigens of *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis*, and group B streptococcus. Latex particle agglutination is superior to countercurrent immunoelectrophoresis in detecting PRP antigen of *H. influenzae* type b in CSF and serum. Nonspecific agglutination of latex particles in serum, urine, and other body fluids may result in an indeterminate test result.[88,183,317,381] A commercial latex particle agglutination kit containing antibody-coated latex particles for *H. influenzae* type b, *S. pneumoniae*, and *N. meningitidis* serogroups is available. In the multicenter pneumococcal meningitis surveillance study, latex agglutination was positive in 49 (66%) of 74 CSF specimens that grew *S. pneumoniae* and in 4 of 14 CSF specimens that were culture negative.[16] The U.S. Food and Drug Administration (FDA) does not recommend latex agglutination testing of urine of infants for group B streptococcus as a method for inferring invasive disease with this organism. Latex agglutination of urine for group B streptococcus or *N. meningitidis* should be avoided because of the high frequency of false-positive results.

The clinical utility of rapid antigen detection in CSF has been questioned in recent years since the decline in frequency of invasive infections caused by *H. influenzae* type b. A positive test response rarely alters the approach to therapy. Bacterial antigen tests should be considered for patients with suspected bacterial meningitis whose initial CSF Gram stain was negative and whose culture was negative after 48 hours of incubation.[240,281] Finlay and colleagues[127] suggested that latex agglutination testing of CSF be used only when the Gram stain is consistent with meningococci. In the latter case, clarifying the meningococcal serotype quickly may have implications in large outbreaks for recommending meningococcal vaccine for type A, C, Y, or W135 disease.

The rapidity with which results of bacterial antigen tests are obtained renders them tempting as a means to establish an early diagnosis. The degree to which they affect clinical decisions is unclear. Performing these tests is unnecessary for every patient suspected to have bacterial meningitis, but they could play a role in certain circumstances, such as when a patient's clinical presentation suggests bacterial meningitis and pretreatment with antibiotics or with a traumatic lumbar puncture. Antigen detection is useful in developing countries, where CSF culture yields are lower.[93,200]

Standard or sequential-multiplex polymerase chain reaction (PCR) has been shown to be useful in identification of infecting pathogens in patients who have previously received antibiotics or in resource-poor

TABLE 31-8 **Cerebrospinal Fluid Findings in Infectious and Inflammatory Diseases of the Central Nervous System and Meninges**

Condition	Pressure (mm H_2O)	Leukocytes/μL	Protein (mg/dL)	Sugar (mg/dL)	Specific Findings
Acute bacterial meningitis	Usually elevated; average 300	Several hundred to >10,000; usually a few thousand; occasionally <100 (especially meningococcal or early in disease); PMLs predominate	Usually 100-500, occasionally >1000	<40 in more than half the cases	Organism usually seen on smear or recovered on culture in >90% of cases
Subdural empyema	Usually elevated; average 300	<100 to a few thousand; PMLs predominate	Usually 100-500	Normal	No organisms on smear or by culture unless concurrent meningitis
Brain abscess	Usually elevated	Usually 10-200; fluid rarely is acellular; lymphocytes predominate	Usually 75-400	Normal	No organisms on smear or by culture
Ventricular empyema (rupture of brain abscess)	Elevated	Several thousand to 100,000; usually >90% PMLs	Usually several hundred	Usually <40	Organisms may be seen on smear or cultured
Cerebral epidural abscess	Slight to modest elevation	Few to several hundred or more cells; lymphocytes predominate	Usually 50-200	Normal	No organisms on smear or by culture
Spinal epidural abscess	Usually reduced with spinal block	Usually 10-100; lymphocytes predominate	Usually several hundred	Normal	No organisms on smear or by culture
Thrombophlebitis (often associated with subdural empyema)	Often elevated	Few to several hundred; PMLs and lymphocytes	Slightly to moderately elevated	Normal	No organisms on smear or by culture
Bacterial endocarditis (with embolism)	Normal or slightly elevated	Few to <100; lymphocytes and PMLs	Slightly elevated	Normal	No organisms on smear or by culture
Acute hemorrhagic encephalitis	Usually elevated	Few to >1000; PMLs predominate	Moderately elevated	Normal	No organisms on smear or by culture
Tuberculous infection	Usually elevated	Usually 25-100, rarely >500; lymphocytes predominate except in early stages when PMLs may account for 80% of cells	Nearly always elevated; usually 100-200; may be much higher if block in CSF flow	Usually reduced; <50 in 75% of cases	Acid-fast organisms may be seen on smear of protein coagulum (pellicle) or recovered from inoculated guinea pig or by culture
Cryptococcal infection	Usually elevated	Average 50 (0-800); lymphocytes predominate	Average 100; usually 20-500	Reduced in more than half of cases; often higher in patients with concomitant diabetes mellitus	Organisms may be seen in India ink preparation and on culture (Sabouraud medium); usually grow on blood agar; may produce alcohol in CSF from fermentation of glucose
Syphilis (acute)	Usually elevated	Average 500; usually lymphocytes; rarely PMLs	Average, 100; gamma-globulin often high, with abnormal colloidal gold curve	Normal (rarely reduced)	Positive reagin test result for syphilis; spirochete not demonstrable by usual techniques of smear or by culture
Sarcoidosis	Normal to considerably elevated	0 to <100 mononuclear cells	Slight to moderate elevation	Normal	No specific findings

PMLs, polymorphonuclear leukocytes.

TABLE 31-9 **Comparison of Cerebrospinal Fluid Findings in Patients with Untreated and Pretreated Meningitis**

	Untreated	Pretreated
No. patients	143	91
Total white blood cell count? 10^3		
Mean ± 1 SD	4.9 ± 6.5	4.1 ± 5
Range	0-55	0.006-25.5
Percentage polys		
Mean ± 1 SD	84 ± 21	81 ± 25

Mean ± 1 SD	226 ± 228	174 ± 193
Range	13-2290	10-1640
Culture positive	135	71
Gram stain positive	114	62

settings.[76,82,200,215,235] PCR analysis of CSF has been used to detect microbial DNA in patients with bacterial meningitis. Primers are available for the detection of *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b simultaneously. Species-specific amplicons have been detected in 89 percent of patients with proven streptococcal, meningococcal, or *H. influenzae* type b meningitis.[293] No false-positive results were noted.

Multiplex real-time PCR or broad-range PCR aimed at the 16S ribosomal RNA gene of eubacteria is promising for the detection of pathogens from CSF. The detection rate was substantially higher with PCR than with cultures in patients who had previously received antibiotics.[82] However, the limit of detection differs between assays. Real-time PCR has been shown to detect as few as two copies of *E. coli*, *N. meningitidis*, and *S. pneumoniae*, 16 copies of *L. monocytogenes*, and 28 copies of group B streptococcus,[82] whereas the sensitivity for broad-range 16S ribosomal DNA PCR was 10 to 200 organisms per milliliter of CSF.[84,85] The time needed for the whole process from DNA extraction to the end of real-time PCR was 1.5 hours,[82] an attractive time frame for its application in clinical practice.

A Gram stain–specific, probe-based, real-time PCR using 16S ribosomal RNA has been shown to allow simultaneous detection and discrimination of clinically relevant gram-positive and gram-negative bacteria directly from blood samples,[200] which might provide more rapid and accurate diagnosis of bacterial infection in infants and children. In addition, sequential PCR-based serotyping of *S. pneumoniae* using serotype-specific primers could improve ascertainment of pneumococcal serotype distribution in settings in which prior use of antibiotics is high.[200] Dicuonzo and associates[99] also documented the great sensitivity of oligoprobes on amplified DNA for the diagnosis of *H. influenzae*, streptococcal, and *Mycobacterium tuberculosis* meningitis. No false-negative results occurred in culture-positive CSF specimens. The possible addition of gene microarray technology offers the potential to probe for multiple different bacterial species simultaneously.[175]

PCR also is useful in rapidly documenting viral antigens within CSF, thus reducing the use of antibiotics in selected patients who are treated for presumptive bacterial disease but who may have viral meningitis.[305,320,371]

Measurement of C-reactive protein (CRP) has been proposed as a test that may be valuable in distinguishing bacterial from viral meningitis. In some studies, overlap in CRP determinations between these groups of patients has been observed and one cannot rely on the CRP result to distinguish bacterial from viral meningitis with sufficient certainty.[152] Nonetheless, serum CRP was superior to CSF parameters in distinguishing gram-negative bacterial from viral meningitis.[343] Among 92 patients with viral meningitis, 93 percent had serum CRP levels within the normal range (<20 mg/L). Only one child with gram-negative bacterial meningitis had a serum CRP value within the normal range.

Elevated serum concentrations of the polypeptide procalcitonin were shown to be useful in differentiating between bacterial and viral meningitis. At a threshold of 0.5 ng/mL, procalcitonin had a sensitivity of 99 percent and a specificity of 83 percent by one report and has been incorporated into the Meningitest (see later).[104]

Numerous metabolic changes have been reported to occur in the CSF and blood of patients with meningitis. CSF lactate has been noted to be elevated significantly in patients with bacterial meningitis. The increase in CSF lactate apparently is related to decreased cerebral blood flow, cerebral hypoxia, and a change to anaerobic metabolism by the brain. Concentration of CSF lactate tends to parallel the CSF cellular response.[307] Although the concentration of CSF lactate in patients with bacterial meningitis generally is greater than that in patients with aseptic meningitis, such is not always the case. In some patients with aseptic meningitis, CSF lactate has been in the range generally observed in patients with bacterial infections. Conversely, in patients who proved to have bacterial meningitis but who had equivocal clinical and CSF findings, measurement of CSF lactate failed to differentiate bacterial from nonbacterial infection.[307] The determination of the concentration of CSF lactate cannot be used reliably to differentiate viral from bacterial meningitis in an individual patient.[211]

Depression of the pH of CSF also has been described in patients with bacterial meningitis. The depression of pH in CSF is more transient than is the elevation of CSF lactic acid, and its measurement is of even less value in the differential diagnosis.

Lactate dehydrogenase, creatine phosphokinase, and aspartate transaminase may be elevated in patients with bacterial meningitis. In some cases, total lactate dehydrogenase activity within CSF may be similar in patients with bacterial and aseptic meningitis but lactate dehydrogenase isoenzymic analysis may permit differentiation of bacterial from nonbacterial infection. This procedure is time consuming and cumbersome and does not permit establishing a specific etiologic diagnosis in any patient.[266]

Despite the application of impeccable clinical judgment, examination of CSF, and use of one or more of the

rapid diagnostic techniques, situations arise in which differentiation of bacterial from aseptic meningitis remains problematic. In these cases, a predominance of polymorphonuclear leukocytes generally is found in the CSF, the CSF cell count is less than 100 cells/mm^3, the CSF glucose concentration is normal or nearly so, and the Gram stain result is negative. Most children with aseptic meningitis have a predominance of polymorphonuclear leukocytes on their initial CSF examination.[267] In addition, although patients exhibit signs and symptoms suggestive of meningitis, they do not appear acutely ill. Some investigators have advocated withholding antibiotic therapy in these patients and repeating the lumbar puncture after 6 to 12 hours of close observation.[3,116] Usually, the repeated examination of CSF either substantiates the impression of aseptic meningitis (a shift to a lymphocytic differential is noted) or points more conclusively to a bacterial process. This course of action is not recommended if the patient has been pretreated with antibiotics or is younger than 1 year old. Occasionally, children have a mild CSF pleocytosis, which may have a predominance of polymorphonuclear leukocytes, after they experience seizures.[391,393] Generally, CSF abnormalities should not be attributed to seizures, unless other causes of CNS inflammation have been excluded.

Other approaches to differentiate bacterial from viral meningitis have been suggested. Evaluation of CSF ferritin concentration has been proposed as a test with considerable predictive value. CSF ferritin concentration is significantly elevated in pediatric patients with bacterial meningitis compared with those with viral meningitis.[202] Using a proposed cutoff of 15.6 ng/mL of CSF ferritin, the test had a sensitivity of 96.2 percent and a specificity of 96.6 percent in differentiating bacterial from viral meningitis.

The ability to distinguish between bacterial and nonbacterial aseptic meningitis in infants and children in the emergency department could contribute to limiting hospital admissions or unnecessary use of antibiotics. The bacterial meningitis score was developed for assessing infants and children with meningitis, and outpatient management might be considered for children who had pleocytosis (7 cells/μL or more) and none of the following five criteria on presentation (history of a seizure with the illness, blood neutrophil count of at least 10×10^3 cells/μL, positive CSF Gram stain, CSF protein of at least 80 mg/dL, or CSF neutrophil count of at least 1×10^3 cells/μL), but this proposed diagnostic tool achieved 95 percent sensitivity and failed to identify 5 patients with bacterial meningitis.[103,269] This tool, called the Meningitest, was refined with incorporation of a serum procalcitonin level of greater than or equal to 0.5 ng/mL and was claimed to have the sensitivity of 100 percent and specificity of 37 percent.[104] The usefulness of both the bacterial meningitis score and the Meningitest for differentiating between bacterial and aseptic meningitis remains to be determined.

Additional laboratory data are helpful and should be obtained. Blood cultures should be obtained in every patient suspected to have bacterial meningitis. In one prospective study in which blood was obtained for culture from every patient, the cultures were positive in 80 percent of children with *H. influenzae* meningitis, in 52 percent of children with pneumococcal meningitis, and in 33 percent of children with meningococcal meningitis.[114] Forty-four percent of the entire group had received some form of antibiotic therapy before admission to the hospital and before these blood cultures were performed. If these individuals were excluded, positive blood cultures were obtained from 90 percent, 80 percent, and 91 percent of children with meningitis caused by *H. influenzae*, *S. pneumoniae*, and *N. meningitidis*, respectively.

A thorough search for foci of infection adjacent to or remote from the meninges should be conducted. Repetitive neurologic evaluation also should be performed, and appropriate laboratory studies should be undertaken to define the extent of neurologic dysfunction.

When the concentration of bacteria within the blood is high, a Gram-stained smear of a buffy coat obtained from the blood may reveal the presence of microorganisms. If petechial lesions are present, a smear of the lesions after puncture with a small lancet may reveal microorganisms on Gram stain. A chest radiograph may be helpful in disclosing a focus of infection.

Radioisotope scanning may be helpful in selected patients, such as patients with a leak of CSF. The pattern of distribution of radioactivity recorded by gamma camera coincides with the accumulation of purulent material. Increased concentration of isotope may relate to the inflammatory response within the meninges or in the periventricular region or to alteration in the blood-brain barrier.[157] Localized concentrations of radionuclide may be seen in children with meningitis, most likely as a result of cerebral vasculitis or infarction.[102] Confirmation of impaired cerebral circulation, including occlusion and narrowing of arteries, sluggish circulation, and retrograde flow, has been described.[141] In these studies, resolution of the arterial lesions was shown in subsequent angiograms in two patients, despite the persistence of neurologic deficits; these findings prompted the authors to suspect vascular spasm at the earlier stage of disease. Hydrocephalus contributed to sluggish circulation through intracerebral vessels in two patients. At least transient disturbance in the circulation of CSF was noted in 45 percent of patients with meningitis, but persistent hydrocephalus is a rare complication of purulent meningitis.[364]

Computed tomography (CT) and magnetic resonance imaging (MRI) are noninvasive techniques that permit the prospective and repetitive assessment of children with meningitis. These techniques permit detection of ventricular dilation, subdural effusion, decrease in brain mass, and presence of vascular lesions or of brain infarcts (Fig. 31-5). With these procedures, ventricular dilation may be noted acutely in many children who never develop hydrocephalus after recovery from their disease.

CT is widely available and useful for rapid assessment of hydrocephalus, mass lesions, hemorrhage or acute brain edema prior to lumbar puncture. In contrast, MRI is required to detect more subtle findings. MRI is more sensitive for assessing CSF involvement, leptomeningitis, empyema, ventriculitis, and infarctions but is not as widely available and can be logistically challenging to obtain in the acutely ill patient. Noncontrast CT and MRI can be normal in early cases of bacterial meningitis. Administration of a contrast agent may be helpful to

FIGURE 31-5 ■ CT scan of a 2-year-old child with bacterial meningitis. Moderately severe ventricular dilation and the presence of bilateral extracerebral fluid collections overlying the convexities of the brain (subdural effusions) are noted. Note the several prominent vessels that run through the subdural space.

detect meningeal enhancement, with MRI being more sensitive than CT. Meningeal enhancement, however, is not specific to the diagnosis of bacterial meningitis and can be seen with other diagnoses, such as leptomeningeal carcinomatosis. Fluid-attenuated inversion recovery (FLAIR)-weighted MRI can demonstrate high signal in the subarachnoid space, reflecting high protein content in the CSF, but high signal in the subarachnoid space can also be seen with leptomeningeal carcinomatosis and subarachnoid hemorrhage. The findings of rhombencephalitis suggest *L. monocytogenes* as the likely causative organism.

The most important role of neuroimaging is to identify potential complications of bacterial meningitis, such as infarction, hydrocephalus, ventriculitis, brain empyema, abscess, and venous sinus thrombosis. Neuroimaging (MRI with gadolinium contrast) may be indicated in the following situations: (1) focal neurologic signs, (2) persistently positive CSF cultures despite administration of appropriate antibiotic therapy, (3) persistent elevation of CSF polymorphonuclear leukocytes (>30% to 40%) after more than 10 days of therapy, and (4) recurrent meningitis.

TREATMENT

Antimicrobial Therapy

Prompt treatment of bacterial meningitis with an appropriate antibiotic is essential. Several retrospective and prospective studies showed that delay in antibiotic treatment was associated with adverse outcomes.[21,200,247] In patients with suspected bacterial meningitis for whom immediate lumbar puncture is delayed due to pending brain imaging study or the presence of disseminated intravascular coagulation, blood cultures must be obtained and antimicrobial treatment should be initiated immediately.

TABLE 31-10 **Likely Pathogens for Meningitis Based on Age, Immunization Status, and Risk Factors**

Age, Immunization Status, Risk Factors	Likely Pathogens
<1 mo	Group B streptococci, *E. coli*, *L. monocytogenes* (neonatal pathogens)
1-3 mo	
No immunization or one dose of primary immunization	Neonatal pathogens, *S. pneumoniae*, *N. meningitidis*, *H. influenzae*
3-6 mo	
No immunization	*S. pneumoniae*, *N. meningitidis*, *H. influenzae*
At least two doses of Hib-OMP vaccine	*S. pneumoniae*, *N. meningitidis*
>7 mo to 5 yr	
No immunization	*S. pneumoniae*, *N. meningitidis*, *H. influenzae*
Primary immunization completed	*S. pneumoniae* (non-PCV serotypes), *N. meningitidis*
6-21 yr	*S. pneumoniae*, *N. meningitidis*
CSF leak, cochlear implant, nephrotic syndrome	*S. pneumoniae*
Complement deficiencies	*S. pneumoniae*, *N. meningitidis*
Asplenia, sickle cell disease	*S. pneumoniae*, *N. meningitidis*, *H. influenzae*

Antibiotic selection should include consideration of such factors as the likely pathogens, the CSF penetration of the antibiotic, the activity of the drug in purulent CSF, the mode of administration of the drug, and the intrinsic pharmacodynamic relationships of CSF drug concentrations to bactericidal activity.[334] The initial selection always should be made before definitive cultures are available, and empirical antimicrobial regimens should cover likely pathogens based on age of the patient and specific risk factors (Table 31-10) with modification if the CSF Gram stain is positive, as well as based on incidence and susceptibility patterns in the local community.[200]

For many years, ampicillin and chloramphenicol were preferred as the initial empirical therapy for children older than 3 months of age and thought to have bacterial meningitis. Ampicillin and chloramphenicol continue to be effective as initial treatment of bacterial meningitis when organisms are susceptible to these agents, but they are used infrequently. Ampicillin may be given intravenously in a dose of 300 mg/kg/24 hours in six divided doses. An initial bolus of 100 mg/kg is given. Chloramphenicol is administered intravenously in a dose of 100 mg/kg/24 hours in four divided doses. No loading dose of chloramphenicol is required.

The development of third-generation cephalosporins and other antibiotics that have excellent bactericidal activity against *H. influenzae* type b, *N. meningitidis*, and *S. pneumoniae* within the CSF as well as emergence of penicillin-resistant pneumococcal isolates led to the current approaches to initial therapy of childhood meningitis. Cefotaxime and ceftriaxone are included in the empirical treatment regimen of choice in most centers.[204]

Cefotaxime is a third-generation cephalosporin that has a broad spectrum of activity against gram-positive and gram-negative organisms. It possesses a high level of resistance to hydrolysis by β-lactamase. Cefotaxime penetrates the blood-brain barrier and provides bactericidal activity in the CSF equivalent to or greater than that of antibiotics that have been used conventionally for treatment of bacterial meningitis in children.[256] It is an excellent choice for inclusion in empirical therapy in children 1 month old or older but must be used with ampicillin for initial therapy in children younger than 1 month old because *L. monocytogenes* and enterococci are sensitive to ampicillin and cannot be treated with cefotaxime. Cefotaxime is given as a daily dose of 225 to 300 mg/kg/day in three or four divided doses intravenously. The high dosage is preferred by some experts because the higher CSF concentrations achieved by high-dose therapy may be beneficial for patients whose disease may be caused by *S. pneumoniae* when the organisms are of intermediate susceptibility to third-generation cephalosporins.[80]

Ceftriaxone is another third-generation cephalosporin that possesses broad antimicrobial activity against the organisms that cause bacterial meningitis. Ceftriaxone readily penetrates the CSF of patients with inflamed meninges. In patients who receive adjunctive therapy with dexamethasone, meningeal inflammation may be reduced, possibly decreasing the penetration of antibiotics into the CSF. Concentration of ceftriaxone in the CSF of children with bacterial meningitis treated with dexamethasone, however, was similar to that found in children not treated with corticosteroids.[142] The half-life of ceftriaxone in serum is approximately 4 hours; a twice-daily dose regimen provides serum and CSF concentrations far in excess of the minimal bactericidal concentrations of most organisms that cause bacterial meningitis. Several prospective randomized studies demonstrated that ceftriaxone is comparable to ampicillin plus chloramphenicol for the treatment of bacterial meningitis in children.[17,31,55,81,95]

Ceftriaxone therapy has been associated with an increased incidence of diarrhea, which is mild and self-limited. An increased incidence of "gallbladder sludge," or precipitation of ceftriaxone salts in the gallbladder, diagnosed by ultrasound, also occurs and generally is asymptomatic but occasionally is associated with clinical symptoms of cholecystitis.[17,316] Ceftriaxone also has a high protein-binding capacity and can displace bilirubin from albumin in vitro[167] and needs to be used cautiously in neonates.

When ceftriaxone is used for the treatment of bacterial meningitis, it can be administered in a dose of 100 mg/kg/24 hr in two divided doses or one daily dose intravenously. Although a once-daily dose has proved to be effective,[47,136,165] is convenient, and lends itself particularly to home therapy for selected patients (after an initial period of hospitalization), single daily dosing is not advocated; dosing errors, delayed doses, or missed doses undoubtedly occur, and inadequate treatment could result. Although ceftriaxone can be given intramuscularly, a single dose by this route may be impractical.[47] The solution used for intramuscular administration should contain no more than 250 mg/mL. A 15-kg child receiving a daily dose of 80 mg/kg would require 4.8 mL of fluid, a volume too large for injection in a single site in an infant. In addition, for penicillin-nonsusceptible but ceftriaxone-susceptible organisms, administration twice a day may be preferred.[80]

An increasing number of strains of *S. pneumoniae* that are relatively or completely resistant to penicillin and third-generation cephalosporins have been identified.[52] Tan and associates[353] reported a retrospective analysis of five children who had pneumococcal meningitis caused by strains that were penicillin resistant and that had minimal inhibitory concentrations (MICs) to cefotaxime or ceftriaxone of 0.5 to 2 μg/mL compared with strains that were penicillin-resistant but susceptible to cefotaxime or ceftriaxone (MIC ≤0.25 μg/mL); there was no difference in clinical outcome at the time of discharge. The Clinical and Laboratory Standards Institute established the current guidelines for interpreting the MIC for cefotaxime or ceftriaxone for pneumococci isolated from patients with bacterial meningitis. The guidelines indicate that strains with an MIC of 2 μg/mL or greater are considered resistant, strains with an MIC of 1 μg/mL are intermediate, and strains with an MIC of 0.5 μg/mL or less are considered fully susceptible.[265]

Vancomycin in a dose of 60 mg/kg/day (15 mg/kg every 6 hr for children older than 1 month old not to exceed 4 g per day; some experts recommend up to 20 mg/kg every 6 hr for these patients.) is recommended in addition to cefotaxime for empirical therapy of children with meningitis because of the frequency with which penicillin-resistant and cephalosporin-resistant pneumococci have been isolated in recent years worldwide. Vancomycin has been used successfully to treat penicillin-resistant pneumococcal meningitis[48] and experimental models of cephalosporin-resistant pneumococcal meningitis.[139] In eight reports of treatment failures with third-generation cephalosporins, a variety of treatment regimens were used, all successfully. Vancomycin, alone or in combination with rifampin, chloramphenicol, or both, was used most frequently. The recommendation for empirical therapy for bacterial meningitis advocated by the AAP Committee on Infectious Diseases is to include vancomycin in addition to a third-generation cephalosporin in patients aged 1 month or older.[10] If nonsusceptibility to penicillin (MIC ≥0.1 μg/mL) and cephalosporins (MIC >0.5μg/mL) is documented, treatment is continued with vancomycin plus cefotaxime or ceftriaxone (a synergistic effect is achieved when they are used together) with or without rifampin to complete an appropriate course. For pneumococcal meningitis, a serum trough concentration greater than 10 to 15 μg/mL is generally recommended; monitoring of vancomycin peak concentrations is not recommended.

Antibiotic tolerance is the ability of an organism to be susceptible to inhibition of growth (as MIC values show susceptible), but resistant to the killing activity of antibiotics, which differs from conventional resistance when resistance is shown by bacterial growth in the presence of antibiotics, resulting in high MIC.[200] Clinical isolates of *S. pneumoniae* that are tolerant to vancomycin have been reported in the United States.[270] Meningitis caused by a vancomycin-tolerant organism in a patient was treated successfully with cefotaxime (300 mg/kg/day in four divided doses) plus vancomycin (80 mg/kg/day in four divided doses) and rifampin (20 mg/kg/day in two divided doses). Chloramphenicol also may be a suitable alternative for the treatment of these organisms if the pneumococcus proves to be susceptible to this antibiotic. Chloramphenicol therapy, however, was shown to have a significantly greater unsatisfactory outcome for children with meningitis caused by penicillin-resistant pneumococci compared with those with penicillin-susceptible pneumococci, although pneumococcal isolates were susceptible to chloramphenicol with MICs of less than or equal to 4 μg/mL.[138]

Two carbapenem agents, imipenem and meropenem, have been studied in patients with bacterial meningitis. These carbapenems are active against the bacteria that cause meningitis, but the use of imipenem-cilastatin has been associated with drug-induced seizures.[393]

The safety and efficacy of meropenem were compared with those of cefotaxime in a prospective randomized trial of 190 children with bacterial meningitis.[207] Seizures occurred within 24 hours before administration of antibiotic therapy in 16 percent of patients randomly assigned to receive meropenem and in 7 percent of patients randomly assigned to receive cefotaxime. Seizures occurred in patients after administration of therapy in 6 percent of children receiving meropenem and in 1 percent of children receiving cefotaxime. None of these seizures could be attributed to drug therapy. All patients responded to therapy with clinical improvement, and bacterial eradication was proved by repeated lumbar puncture in 100 percent of patients in both groups. No significant difference in short-term outcomes occurred between the two groups. Similarly, the efficacy and safety of meropenem with cefotaxime were compared for the treatment of bacterial meningitis in 258 children who were randomly assigned to the meropenem or cefotaxime group.[273] Clinical cure with or without sequelae was achieved in 97 percent and 96 percent of the meropenem-treated and cefotaxime-treated patients, respectively. At 7 weeks after treatment was concluded, 54 percent of patients treated with meropenem and 58 percent of patients treated with cefotaxime had no sequelae. Seizures were noted in 12 percent of the patients treated with meropenem and in 17 percent of patients treated with cefotaxime; none of the seizures was considered to be drug related. These data suggest that meropenem is effective in the treatment of bacterial meningitis in children. Few children with pneumococcal meningitis in either study had isolates that were nonsusceptible to cefotaxime. No conclusions can be drawn regarding the usefulness of meropenem in treating pneumococcal meningitis caused by isolates with a cefotaxime or ceftriaxone MIC equal to or greater than 2 μg/mL. However, of 20 cefotaxime-resistant *S. pneumoniae* isolates, 4 were intermediate and 13 were resistant to meropenem, suggesting that meropenem may not be a reliable alternative agent for pneumococcal isolates that are highly resistant to penicillin and cephalosporins. Meropenem may be indicated for patients who have meningitis that is caused by organisms resistant to extended-spectrum cephalosporins (e.g., nosocomial meningitis due to extended-spectrum β-lactamases producing gram-negative bacteria), but its efficacy has not been demonstrated.

Cefepime is a fourth-generation cephalosporin that has been studied for the treatment of bacterial meningitis. In vitro, cefepime offers no advantage over cefotaxime or ceftriaxone for penicillin-resistant *S. pneumoniae*.[196] In addition, no in vitro data exist for the efficacy of cefepime against cefotaxime-resistant pneumococci. In two clinical trials, the efficacy of cefepime was found to be equivalent to the efficacy of either cefotaxime or ceftriaxone.[308,309] No penicillin-resistant or ceftriaxone-resistant pneumococci were encountered in either study, however. Cefepime has been used for the treatment of bacterial meningitis as an alternative agent.

Ceftazidime has been efficacious in the treatment of meningitis caused by *P. aeruginosa*.[177,249,299] Cefpirome concentrations in CSF of patients with bacterial meningitis were found to be significantly higher than the minimal bactericidal concentrations for *N. meningitidis*, *H. influenzae*, and *S. pneumoniae*,[391] but studies documenting its effectiveness in large numbers of children have not been done.

Cefoperazone and cefoxitin within CSF may fail to reach concentrations required to kill all susceptible strains of *H. influenzae* and *S. pneumoniae* and cannot be recommended for the treatment of bacterial meningitis in children.[58,124]

Cefuroxime is a second-generation cephalosporin that has been shown to be effective in vitro against *H. influenzae* type b, *S. pneumoniae*, and *N. meningitidis*. Studies showed delayed sterilization of the CSF, and also relapse during or after treatment was higher; and more frequent sensorineural hearing loss occurred than with use of ampicillin, chloramphenicol, cefotaxime, and ceftriaxone.[15,219,221,315] Cefuroxime should not be used to treat bacterial meningitis in children.

Aztreonam is an antimicrobial agent that belongs to the monobactam family of antibiotics. It is effective against most gram-negative organisms, including *P. aeruginosa*. Limited data suggest its efficacy in the treatment of *Pseudomonas* and *H. influenzae* meningitis, suggesting a potential role for this agent in the treatment of patients who are allergic to penicillin and who are infected with these or other gram-negative organisms.[197,220,360]

If a history of *significant* allergy to penicillin or cephalosporin (anaphylaxis, urticaria, exfoliative dermatitis) is documented, vancomycin plus rifampin or aztreonam may be used. A cross-reactivity of 10 to 15 percent has been noted for cephalosporins in penicillin-allergic patients.

When meningitis is caused by *Streptococcus pyogenes*, penicillin or ampicillin provides effective therapy. If meningitis is caused by a penicillin-resistant strain of *S. aureus*, oxacillin or nafcillin 200 mg/kg/24 hr intravenously in

four or six divided doses should be used. Vancomycin is effective against *S. aureus* strains resistant to penicillin and to semisynthetic penicillin derivatives[168] or *S. aureus* meningitis in patients who are penicillin allergic. Vancomycin also may be useful in treatment of meningitis caused by *Flavobacterium meningosepticum*.[100] Metronidazole is effective in treatment of anaerobic infection of the CNS when response to conventional therapy has been suboptimal. A dose of 340 mg/kg/24 hr in four divided doses results in CSF concentrations of greater than 10 μg/mL.[36]

In animal models, the addition of a nonbacteriolytic antibiotic such as rifampin[150] has been associated with a neuroprotective effect, suggesting the possibility of its use as an adjunct therapy. Bottcher and associates[46] showed decreased bacterial cell wall release, a lessened proinflammatory response (including decreased leukocyte recruitment), less free radical formation, and decreased apoptosis and cellular damage after the addition of clindamycin to standard antibiotic therapy.

Table 31-11 provides current recommendations for antibiotic treatment of various microorganisms. An appropriate antibiotic should be continued until the patient is afebrile for 5 days, but for at least 7 to 10 days in every patient. Although some data support a shorter course of therapy, at least 10 days of treatment is recommended for pneumococcal and *H. influenzae* type b meningitis and 7 days for *N. meningitidis* meningitis.[185,232] If clinical improvement is noted within 24 hours, a repeated lumbar puncture is unnecessary, in most cases, during the course of treatment or after treatment has been completed. If infection is caused by *S. pneumoniae* that is resistant to penicillin and to third-generation cephalosporins, a repeated lumbar puncture is recommended at 48 to 72 hours to document bacterial sterilization of the CSF. If clinical improvement is slower than anticipated or is not noted, a repeated examination of the CSF is indicated at any time.

In the 1970s, lumbar puncture frequently was performed at the conclusion of therapy. Data from studies performed at that time (Table 31-12) reveal that WBC counts and protein concentrations within the CSF generally had not returned completely to normal and that the CSF-to-blood glucose ratios may have remained depressed. In every case, Gram stain of the CSF should reveal no organisms and cultures should be sterile. If a lumbar puncture is performed at the conclusion of therapy, we consider re-treatment to be mandatory if organisms are seen or grown. It also may be considered if more than 30 percent of the cells are polymorphonuclear leukocytes, or if the CSF glucose concentration is less than 20 m/dL, and the CSF-to-blood ratio is less than 20 percent (see Table 31-12).

Bacteriologic relapse after treatment of meningitis (particularly that caused by *H. influenzae* and treated with ampicillin) was highlighted in numerous reports.[25,75,78,171,172] Precise assessment of the frequency of relapse in children who have received an appropriate antibiotic to which the organism is susceptible or an appropriate dose intravenously and for an extended period has been difficult. The relapse rate is currently less than 1 percent.

Some physicians have discharged children with meningitis from the hospital before the conclusion of a course of therapy and prescribed home management. Benefits of home therapy include a decreased risk for acquiring nosocomial infection, a return of the child to his or her normal environment sooner, and a decrease in the total cost of therapy. Financial savings of outpatient, once-daily ceftriaxone for pediatric meningitis have been estimated to be $200 per day.[289]

Fifty-four children with bacterial meningitis were treated as outpatients for 1 to 8 days (mean 4.6 days) with intramuscular ceftriaxone given once daily.[47] Each dose was given in conjunction with a physician's examination. Each child had to be afebrile for 24 to 48 hours before initiation of home therapy, free of neurologic dysfunction except for auditory or vestibular dysfunction, and without evidence of inappropriate secretion of ADH before being considered for outpatient therapy. No child required readmission or developed neurologic sequelae or relapse. A retrospective review of 26 patients with meningitis or other serious bacterial infections who received some portion of their therapy as an outpatient with ceftriaxone revealed that none of the patients experienced relapse or recurrence.[289]

Waler and Rathore[378] suggest 10 criteria for considering outpatient therapy for children with bacterial meningitis: (1) the child has received inpatient therapy for at least 6 days, (2) the child is afebrile for at least 24 to 48 hours before initiation of outpatient therapy, (3) the child has no significant neurologic dysfunction or focal findings, (4) the child has no seizure activity, (5) the child is clinically stable, (6) the child is taking all fluids by mouth, (7) the first dose of outpatient antibiotic is received in the hospital, (8) the antibiotic is administered in the office or emergency department setting or by qualified home health nursing, (9) daily examination is performed by a physician, and (10) parents are reliable and have transportation and a telephone. The dose of ceftriaxone of 100 mg/kg/24 hr intramuscularly may need to be aliquoted to account for the volume of diluents needed to achieve a concentration of no greater than 250 mg/mL.

H. influenzae type b organisms have been recovered from the throats of patients after completion of a course of treatment for *H. influenzae* type b meningitis. When members of a household to which the patient will return include children 4 years of age or younger, the patient should be given rifampin 20 mg/kg once daily for 4 days, to prevent the occurrence of secondary cases. Children with meningococcal meningitis also should receive chemoprophylaxis to eradicate nasopharyngeal carriage before discharge, unless they were treated with cefotaxime or ceftriaxone (see Prevention).

Adjunctive Therapy

As described earlier, the pathogenesis and subsequent sequelae of bacterial meningitis are as much a consequence of the host response to infection as of the bacterial organisms themselves. Anti-inflammatory and anti-osmotic agents used as adjuncts to antimicrobial therapy may decrease the degree of tissue injury during the course of the disease.

TABLE 31-11 **Recommendations for Antibiotic Therapy for Bacterial Meningitis**

Organism	Antibiotic(s)	Recommended Dosages (IV)
Bacteroides fragilis	Metronidazole	30 mg/kg/day in 4 dd
	Chloramphenicol	100 mg/kg/day in 4 dd
Bacteroides other than *B. fragilis*	Penicillin G	300,000 U/kg/day in 6 dd
Clostridium	Penicillin G	300,000 U/kg/day in 6 dd
Corynebacterium	Penicillin G	300,000 U/kg/day in 6 dd
	Erythromycin	50 mg/kg/day in 4 dd
Enterobacter, Klebsiella, Escherichia coli[*]	Cefotaxime	200 mg/kg/day in 4 dd
	Ceftriaxone	100 mg/kg/day in 2 dd
	Meropenem	120 mg/kg/day in 3 dd
	Ampicillin	300 mg/kg/day in 6 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	Amikacin	15 mg/kg/day in 3 dd
Haemophilus influenzae	Cefotaxime	200 mg/kg/day in 4 dd
	Ceftriaxone	100 mg/kg/day in 1 or 2 dd
	Chloramphenicol	100 mg/kg/day in 4 dd
	Ampicillin	300 mg/kg/day in 6 dd
Listeria monocytogenes	Ampicillin	300 mg/kg/day in 6 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	TMP-SMX	20 mg/kg/day in 4 dd (TMP component)
Neisseria meningitidis	Penicillin G	300,000 U/kg/day in 6 dd
	Cefotaxime	200 mg/kg/day in 4 dd
	Ceftriaxone	100 mg/kg/day in 1 or 2 dd
Proteus mirabilis (indole-negative)	Ampicillin	300 mg/kg/day in 6 dd
P. mirabilis (indole-positive)	Cefotaxime	200 mg/kg/day in 4 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	Amikacin	22.5 mg/kg/day in 3 dd
	Ticarcillin	300 mg/kg/day in 4-6 dd
Pseudomonas	Ceftazidime	150-200 mg/kg/day in 3 dd
	Meropenem	120 mg/kg/day in 3 dd
	Ticarcillin	450 mg/kg/day in 4 or 6 dd
	Piperacillin	300 mg/kg/day in 4 or 6 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	Amikacin	15-20 mg/kg/day in 3 dd
Salmonella	Cefotaxime	200 mg/kg/day in 4 dd
	Ampicillin	300 mg/kg/day in 6 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	Chloramphenicol	100 mg/kg/day in 4 dd
Staphylococcus aureus (penicillinase-negative)[†]	Penicillin G	300,000 U/kg/day in 6 dd
S. aureus (penicillinase-positive)[†]	Oxacillin or nafcillin	200 mg/kg/day in 4 or 6 dd
S. aureus (resistant to semisynthetic penicillins)	Vancomycin *plus*	80 mg/kg/day in 4 dd
	Rifampin	20 mg/kg/day in 2 dd
Staphylococcus (coagulase-negative)	Vancomycin	80 mg/kg/day in 4 dd
	Rifampin	20 mg/kg/day in 2 dd
Streptococcus pneumoniae[†]	Cefotaxime/ceftriaxone	225-300 mg/kg/day in 3 or 4 dd/100 mg/kg/day in 1 or 2 dd
	Vancomycin	60-80 mg/kg/day in 4 dd
	Rifampin[‡]	20 mg/kg/day in 2 dd
	Penicillin G	300,000 U/kg/day in 6 dd
	Chloramphenicol	100 mg/kg/day in 4 dd
Unknown (<1 mo old)	Ampicillin *plus*	300 mg/kg/day in 6 dd
	Cefotaxime *or*	200 mg/kg/day in 4 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
Unknown (>1 mo old)	Cefotaxime *or*	225-300 mg/kg/day in 4 dd
	Ceftriaxone *plus*	100 mg/kg/day in 1 or 2 dd
	Vancomycin	60-80 mg/kg/day in 4 dd
	Nafcillin or oxacillin (if question of staphylococcal infection)	200 mg/kg/day in 6 dd

*Trimethoprim-sulfamethoxazole (TMP-SMX) in a dose of 20 mg/kg/day (TMP) and 100 mg/kg/day (SMX) IV in 4 dd has been used successfully in selected patients with gram-negative enteric meningitis.

†Vancomycin may be provided in a dose of 80 mg/kg/day in 4 dd IV (20 mg/kg every 8 hr, or 60 mg/kg/day in 3 dd in older adolescents) if patients are allergic to penicillin or penicillin derivatives or, in the case of *S. pneumoniae*, for multidrug-resistant pneumococci or pneumococci that are highly resistant to penicillin. In these cases, addition of rifampin may be considered.

‡Should never be used alone.

dd, divided doses.

Note: In the 1970s, lumbar puncture frequently was performed at the conclusion of therapy. Data from studies performed at that time (see Table 31-12) reveal that white blood cell counts and protein concentrations within the CSF generally had not returned completely to normal and that the CSF-to-blood glucose ratios may have remained depressed. In every case, Gram stain of the CSF should reveal no organisms and cultures should be sterile. If a lumbar puncture is performed at the conclusion of therapy, we consider re-treatment to be mandatory if organisms are seen or grown. It also may be considered if more than 30 percent of the cells are polymorphonuclear leukocytes or if the CSF glucose concentration is less than 20 m/dL and the CSF-to-blood ratio is less than 20 percent.

TABLE 31-12 **Cerebrospinal Fluid Findings at Conclusion of Antibiotic Treatment**

	Total White Blood Cell Count		Polymorphonuclear Leukocytes (%)		CSF-to-Blood Protein (mg/dL)		Glucose (mg/dL)		CSF-to-Blood Glucose Ratio (%)	
	MEAN ±SD	RANGE	MEAN ±SD	RANGE	MEAN ±SD	RANGE	MEAN ±SD	RANGE	MEAN ±SD	RANGE
Total group	41 ± 80	0-850	5.5 ± 12	0-90	46 ± 72	7-970	47 ± 12.7	21-91	55.7 ± 17	23-156
H. influenzae	53 ± 98	0-850	5.5 ± 11	0-90	43 ± 37	10-334	47 ± 13	31-100	55 ± 17	31-100
H. influenzae (ampicillin)	56 ± 107	0-850	5.9 ± 12	0-90	44 ± 43	13-334	46 ± 14	21-91	53 ± 17	33-89
H. influenzae (chloramphenicol)	49 ± 83	0-325	5.1 ± 10.7	0-50	41 ± 26	7-127	48 ± 11	27-90	57 ± 13	30-100

CSF, cerebrospinal fluid; SD, standard deviation.

Anti-inflammatory Therapy

Research studies seek additional therapies that could be used to help reduce further mortality, morbidity, or both. Five main areas serve as the targets for therapeutic development: (1) modulation of bacterial killing and the release of bacterial products by using nonbacteriolytic antibiotics such as rifampin, (2) host recognition of bacteria or its products and the initiation of the inflammatory response, (3) modulation of the inflammatory response with adjuvant dexamethasone, (4) inhibition or interruption of the host inflammatory/neurotoxic mediators, and (5) modulation of the apoptotic pathways.[148,162,198,210] Inhibitors of inflammatory mediators and mediator effector molecules such as TNF-α, matrix metalloproteinases, and nitric oxide and antioxidants, neuroprotective factors (melatonin and brain-derived neurotrophic factor), and other anti-inflammatory therapies (triptans) are being studied in experimental animal models of bacterial meningitis.[149,198,210] Although their use is attractive theoretically because of the damage produced by the inflammatory cascade (Fig. 31-3), none has emerged as a realistic potential candidate for general clinical use at present.

Corticosteroids

Corticosteroids have been suggested as an adjunct to therapy for bacterial meningitis because they may (1) decrease intracranial pressure by decreasing meningeal inflammation and brain water content; (2) modulate the production of cytokines, which lessens the meningeal inflammatory response; and (3) decrease the incidence of sensorineural hearing loss or other neurologic complications of meningitis.[218,272]

Corticosteroids may play a role in acute management of increased intracranial pressure and cerebral herniation, although no data specifically indicate that corticosteroids decrease cerebral edema caused by bacterial meningitis. Dexamethasone therapy in children with bacterial meningitis was shown to decrease opening lumbar CSF pressure 12 hours after administration of the first dose, but this effect was lost by 24 hours of treatment.[270] The significance of these findings is unclear because the corticosteroids were not given as specific therapy for increased intracranial pressure and most of the subjects were not showing signs of impending herniation.

In experimental *H. influenzae* meningitis, administration of dexamethasone 1 hour before, but not 1 hour after, administration of ceftriaxone was associated with significantly reduced TNF-α concentration and indices of inflammation in the CSF.[261]

Administration of dexamethasone has been associated with decreased concentration in CSF of prostaglandin E_2 and decreased leakage of some proteins from serum into CSF in rabbits with experimental pneumococcal meningitis.[186] Among patients with bacterial meningitis, steroid-treated patients had significantly lower concentrations of IL-1β, TNF-α, PAF, and prostaglandin E_2 in their CSF than those of patients who received antibiotics alone.[262,272] Patients tend to become afebrile sooner when they receive dexamethasone, but they have an increased incidence of secondary fevers.[16,376]

Although the understanding of the pathophysiologic events associated with initiation of the acute inflammatory response has been enhanced by more recent data, the ability of dexamethasone to reduce long-term complications of bacterial meningitis in pediatric patients remains controversial. In a prospective, randomized, double-blinded, placebo-controlled study evaluating adults in Europe with bacterial meningitis, de Gans and colleagues[92] showed a decrease in mortality rates in all patients and in unfavorable outcomes in patients with pneumococcal meningitis. By contrast, no pediatric studies of the use of dexamethasone for treatment of bacterial meningitis have shown an overall change in mortality rates.

In randomized, placebo-controlled trials of dexamethasone as adjunctive therapy in bacterial meningitis[218,272,314,376] and in retrospective studies[159,195] published since 1988, 68 percent (227 of 333) of corticosteroid recipients in the six randomized trials had meningitis caused by *H. influenzae* type b; the remaining 32 percent had meningitis caused by *S. pneumoniae* (50 of 333) or *N.*

meningitidis (56 of 333).[290] A meta-analysis of nine controlled trials published before 1991 failed to document a reduced risk for neurologic abnormality at hospital discharge or follow-up examination.[178] A more recent meta-analysis of randomized clinical trials of dexamethasone as adjunctive therapy for bacterial meningitis suggests a beneficial effect of this agent for *H. influenzae* meningitis and a possible beneficial effect in preventing severe hearing loss in *S. pneumoniae* meningitis, but only if it is given early.[243]

Most patients with *S. pneumoniae* meningitis in the studies that were reviewed were not treated with vancomycin. This issue is important because the penetrance of vancomycin across the blood-brain barrier is not optimal, and selected studies show that it is reduced further when dexamethasone is used concomitantly.[16,49,250] Despite the theoretical clinical concerns, CSF concentrations of vancomycin and ceftriaxone are adequate for treatment of penicillin-susceptible and penicillin-nonsusceptible *S. pneumoniae* when dexamethasone is given at recommended dosages.[112,208]

Administration of dexamethasone immediately before the initiation of cefotaxime therapy was associated with a reduced incidence of neurologic sequelae (14% compared with 38% in patients receiving cefotaxime alone).[272] These investigators found no significant difference in auditory sequelae compared with control subjects. The frequency of neurologic sequelae in placebo-treated patients, however, was significantly higher than that noted in other studies.[16,314,376]

In contrast, other studies failed to show a significant reduction in the incidence of neurologic sequelae in comparisons of corticosteroid-treated and placebo-treated patients.[218,314] A prospective, multicenter, placebo-controlled study evaluated 143 children with bacterial meningitis caused by *H. influenzae* type b (58%), *S. pneumoniae* (23%), and *N. meningitidis* (17%).[376] Patients were treated with ceftriaxone and placebo or ceftriaxone and dexamethasone administered within 4 hours of the first dose of antibiotics. No significant difference in neurologic or developmental outcome was found between patients who received corticosteroids or placebo.

Sensorineural hearing loss is a significant sequel of bacterial meningitis. In the two randomized studies,[218] patients treated with dexamethasone were significantly less likely to have moderate or severe bilateral sensorineural hearing loss; however, in one study, patients were treated with cefuroxime, which has been shown to result in delayed sterilization of CSF and a higher rate of hearing loss compared with ceftriaxone.[315] An additional 100 infants and children with bacterial meningitis were treated with ceftriaxone for 10 days and either dexamethasone or placebo for 4 days. A significant reduction in moderate to severe hearing loss in children with *H. influenzae* type b meningitis (p <.001) was reported. No significant differences in other neurologic sequelae were found between the two groups. In addition, two patients receiving dexamethasone developed gastrointestinal bleeding severe enough to require transfusion and two others developed heme-positive stools.[218] Odio and associates found no significant difference in the incidence of moderate or severe hearing impairment between placebo and corticosteroid groups (16% and 6%), respectively.[272]

The Swiss Meningitis Group[314] found that treatment of children with dexamethasone 10 minutes before administration of ceftriaxone and then for 2 days subsequently resulted in persistent hearing loss in 5 percent (three) of children who had received dexamethasone and in 15 percent (eight) of children who received placebo, a difference that was not significant. One child treated with corticosteroid and five children treated with placebo had unilateral hearing loss only. The group also documented a transient mild to moderate hearing impairment in five children treated with dexamethasone and four children treated with placebo; in six of the nine children, the impairment was caused by a conductive disturbance. Dexamethasone did not alter the incidence or natural history of the transient hearing impairment.

In a multicenter study,[376] audiologic measurements were made early in the course of the disease (within 24 hours of admission) and 6 weeks to 12 months after recovery from disease. The authors found no significant difference in the incidence of persistent moderate or severe hearing loss between children who received dexamethasone within 4 hours of antibiotics and children who received placebo, with the exception of bilateral deafness in children with *H. influenzae* type b meningitis (5 of 72 in the placebo-treated group vs. 0 of 67 in the dexamethasone-treated group; p = .02). The overall incidence of moderate to severe hearing loss was 14.7 percent (10.3% unilateral and 4.4% bilateral) in the dexamethasone-treated group and 22.9 percent (13.5% unilateral and 9.4% bilateral; p = .33 for bilateral loss) in the placebo-treated group. These authors found that 22 children (8 in the dexamethasone-treated group and 14 in the placebo-treated group) had bilateral moderate or severe hearing loss at the initial evaluation. Only one child with *H. influenzae* meningitis and unilateral deafness at initial examination progressed to bilateral deafness. At follow-up, the resolution of hearing loss was nearly identical for each group, with 8 of the 22 children having normal hearing at follow-up, 5 having unilateral deafness, and 9 having bilateral deafness.

These results suggest that hearing loss occurs early in the course of meningitis and that early auditory brain stem response results need to be interpreted cautiously with regard to long-term audiologic sequelae. A strong relationship was noted between hearing loss early in the disease and a low concentration of CSF glucose at manifestation of meningitis, a finding that has been reported previously.[101]

Data from animal studies highlight a potential negative effect of dexamethasone therapy on neuronal injury, including hippocampal apoptosis in experimental animals with pneumococcal and *E. coli* meningitis who received dexamethasone.[225,346]

The AAP Committee on Infectious Diseases states that dexamethasone therapy should be considered for pneumococcal meningitis in infants and children 6 weeks old and older.[10] Dexamethasone also is recommended for treatment of infants and children with *H. influenzae* type b meningitis.[10] The reluctance on the part of some experts to recommend dexamethasone for pneumococcal

meningitis is predicated on data that fail to show any diminution in morbidity or mortality rates from meningitis when meningitis is caused by *S. pneumoniae* and dexamethasone is used. Dexamethasone should be used cautiously when vancomycin is used to treat meningitis caused by *S. pneumoniae* that may be resistant to penicillin, third-generation cephalosporins, or both.[49] The CSF concentrations of vancomycin, ceftriaxone, cefotaxime, and rifampin when they are given in dosages recommended for meningitis in children treated with dexamethasone generally are shown to be adequate to treat meningitis caused by most nonsusceptible strains of *S. pneumoniae*. Dexamethasone plus vancomycin may decrease the transport of vancomycin into the CSF of experimental animals with pneumococcal meningitis, but this finding was not observed in nine children who were treated with vancomycin and dexamethasone (0.6 mg/kg/day).[208] Dexamethasone can lead to decreased fever and a misleading impression of clinical improvement, even though sterilization of the CSF has not been achieved.

Dexamethasone should not be used if aseptic or nonbacterial meningitis is suspected; if it is started before the diagnosis of nonbacterial meningitis is made, it should be discontinued immediately. It should not be used in "partially treated" meningitis. No data exist on which to base a recommendation for use of dexamethasone in the treatment of bacterial meningitis in infants younger than 6 weeks of age or in infants with congenital or acquired abnormalities of the CNS, with or without a prosthetic device. One prospective study in infants concluded that adjunctive dexamethasone therapy does not improve the outcome of neonatal bacterial meningitis.[86] If dexamethasone is used, it should be used in all patients, regardless of disease severity, and it should be administered as early as possible in the course of treatment in a dose of 0.15 mg/kg/dose intravenously every 6 hours for no more than 4 days. One study[314] found no difference in children treated for 2 days instead of 4 days with 0.4 mg/kg/dose every 12 hours.

Except for hearing loss after *H. influenzae* type b meningitis, no clear evidence establishes that dexamethasone dramatically alters the long-term sequelae of meningitis, and its use is not without risk for causing adverse events. The markedly decreased frequency of meningitis caused by *H. influenzae* type b and the increased frequency of meningitis caused by *S. pneumoniae* nonsusceptible to penicillin (for which therapy with vancomycin may be necessary) suggest that initiation of dexamethasone should be considered carefully and that the clinician caring for the patient should evaluate the risk-to-benefit ratio of such therapy.

Glycerol

A recent multicenter double-blind randomized study in six Latin American countries showed that adjunctive treatment with oral glycerol 1.5 g/kg every 6 hours for 48 hours prevents severe neurologic sequelae in childhood meningitis (odds ratio 0.31; 95% CI 0.31 to 0.76) compared with placebo.[279] Glycerol is a hyperosmolar agent, and because of its safety, wide availability, low cost, and oral administration, its use as adjunctive treatment in children with bacterial meningitis, particularly in resource-limited settings, is attractive, but subsequent studies in experimental animals and children with bacterial meningitis did not reveal any benefits.[280]

Supportive Care

In addition to antibiotic therapy, management of bacterial meningitis includes measures that apply generally to critically ill children. Careful monitoring and attention to detail are essential. Pulse rate, blood pressure, and respiratory rate should be measured carefully every 15 minutes until stable and then every hour while the patient is in the intensive care unit. Temperature should be measured every 4 hours. A thorough neurologic examination should be done at the time of admission and at least daily thereafter. A rapid assessment of neurologic function should be done several times a day for the first several days of treatment. Body weight should be measured daily for at least the first 3 or 4 days. Head circumference should be measured in children younger than 18 months at the time of admission and repeated daily if concerns about increased intracranial pressure persist.

The following laboratory data are suggested if results of lumbar puncture indicate bacterial meningitis: (1) total peripheral WBC count and differential, (2) hemoglobin concentration, (3) hematocrit, (4) platelet count, and (5) serum electrolytes (serum and urine osmolalities may be useful in selected patients). Urine volume and specific gravity should be monitored. A low WBC count may suggest a poor prognosis. Anemia associated with *H. influenzae* type b septicemia has been reported[329,330] and has been attributed to immune hemolysis of RBCs that are coated with soluble bacterial antigens.

Every child with meningitis should be evaluated carefully to identify inappropriate secretion of ADH, recognize seizure activity, and detect the development of subdural effusions. Determinations of body weight, serum electrolytes (serum and urine osmolalities in selected patients), urine volume, and specific gravity should be made at the time of admission and observed closely (every 6 to 12 hours) for the first 24 to 36 hours that the child is in the hospital and daily for several days thereafter. Initially, the child should receive nothing by mouth because of the risk for vomiting and aspiration. In addition, delivery of all fluid intravenously ensures greater accuracy in measurement of intake and output during the critical early days of therapy. Inappropriate secretion of ADH has been documented in 88 percent of children enrolled in a prospective study of bacterial meningitis.[114] Elevated serum concentrations of ADH in the presence of hyponatremia have been documented by direct measurement of ADH concentration in serum obtained from the same children.[115]

An electrolyte solution containing approximately 40 mEq/L of sodium and chloride, 35 mEq/L of potassium, and 20 mEq/L of acetate or lactate should be administered at a rate of 1000 to 1200 mL/m^2/24 hr in a patient without evidence of dehydration or shock. Fluid restriction is continued until it can be documented (frequently within 2 hours), on the basis of objective measures, that ADH secretion is not a factor or has resolved.

The best indicators of retention of fluid in excess of solute are body weight and serum sodium concentration. As serum sodium concentration approaches normal (135 to 140 mEq/L), fluid administration may be liberalized progressively to normal maintenance levels of 1500 to 1700 mL/m^2/24 hr.

The syndrome of inappropriate secretion of ADH should not be diagnosed in the presence of dehydration. Decreased intravascular volume is a physiologic stimulus for the release of ADH, and its release is not inappropriate. Fluid restriction is not advocated for patients who are dehydrated; rehydration should be performed with careful and frequent assessment of fluid and electrolyte status.

Singhi and colleagues[333] examined the effect of fluid restriction on body water and outcome of 50 consecutive children who had been hospitalized with acute meningitis. These children were divided into two groups: patients with hyponatremia and patients without hyponatremia. Patients in both groups were randomly assigned to receive either normal maintenance or restricted fluids (65% to 70% of the volume of that received by the maintenance subgroup). Eleven to 15 patients were randomly assigned to any of the four subgroups in the study. No significant difference in overall outcome or intact survival was found when comparisons were made between fluid-restricted and non–fluid-restricted groups or within each group between the subgroups that received restricted fluids or maintenance fluids. After combination of the subgroups that received restricted fluids with the subgroups that received maintenance fluids, however, a trend toward higher intact survival and lower mortality rates was noted in the non–fluid-restricted groups. Nonetheless, children who had an extracellular water reduction of 10 mL/kg or greater in 48 hours had a significantly lower intact survival rate (10 of 28, 36%) than that of children with less than 10 mL/kg or no reduction of extracellular water (15 of 22, 64%). The mortality rate also was higher in the former group (7 of 28, 25%) than in the latter group (2 of 22, 9%). The authors concluded that fluid restriction did not improve the outcome of acute meningitis and that a decrease in extracellular water volume at 48 hours may increase the likelihood of having an adverse outcome.

In contrast, in studies of large numbers of children with bacterial meningitis, evidence of inappropriate secretion of ADH correlated significantly (p <.01) with abnormal neurologic findings, even 3 months after discharge, and with low IQ scores.[119] As a result of these findings, coupled with documentation of inappropriate secretion of ADH, a recommendation was made to restrict fluids in patients who are hyponatremic at admission. Fluids are restricted only until evidence of inappropriate secretion of ADH can be excluded (usually within 2 hours). The average patient in subsequent studies[190] was fluid restricted for only 18 hours.

Because cerebral edema and increased intracranial pressure have been noted as major disturbances in seriously ill patients with meningitis and because many of the deaths and some of the sequelae have been related to the effects of cerebral edema and intracranial hypertension, it appears prudent to recommend fluid restriction in patients with hyponatremia who are not dehydrated and liberalization of fluids as soon as the effects of excess ADH secretion have been dissipated (usually <1 day).

Meningitis complicated by shock creates a complex fluid management problem. Shock associated with meningitis is secondary to septicemia and generally is treated with intravenous infusion of large quantities of fluid to maintain blood pressure and adequate tissue perfusion. Patients with meningitis without shock or dehydration benefit from initial fluid restriction to avoid worsening of cerebral edema and severe hyponatremia with subsequent seizures. Children with meningitis and shock should receive sufficient quantities of isotonic fluid to maintain a systolic blood pressure of 80 to 90 mm Hg, a urine output equal to or greater than 500 mL/m^2/24 hr, and adequate cerebral perfusion as indicated by mental status. Central venous pressure monitoring is useful to guide fluid resuscitation and to prevent fluid overload. The addition of albumin (1 g/kg) to intravenously administered fluids may decrease the total volume of fluid needed to maintain adequate perfusion. Vasopressors, such as dopamine, dobutamine, and isoproterenol, also may provide support of blood pressure and perfusion and reduce requirements for intravenously administered fluids.

When increased intracranial pressure is suggested by such signs as progressive lethargy, increased muscle tone, or bulging anterior fontanelle, elevating the head approximately 30 degrees may be helpful. Increased intracranial pressure associated with deterioration in mental status or signs of cerebral herniation may be treated more vigorously with mannitol administered intravenously at 0.5 g/kg infused during 30 minutes and repeated as necessary. If corticosteroids are used for this purpose, the recommended agent is dexamethasone in a dose of 10 to 12 mg/m^2/day in four divided doses for no more than 4 or 5 days.[190] Other supportive measures to ensure appropriate delivery of oxygen and nutrients to the brain include a quiet environment, elective intubation, and the use of sedatives.[32]

Head circumference measurement and transillumination permit assessment of the development of subdural effusions or may suggest other causes for an enlarging head. CT may be helpful in detecting large subdural effusions or hydrocephalus. Because effusions can be considered part of the pathophysiologic changes that occur with bacterial meningitis, obtaining CT scans to evaluate effusions does not need to be part of the routine evaluation of a child with meningitis. Neuroimaging (CT or MRI with contrast) should be performed in children with focal neurologic signs. In children with hemiparesis or quadriparesis, CT or MRI may document cerebrovascular abnormalities. CT also should be performed in children with papilledema on an emergency basis before proceeding with the initial lumbar puncture. *Administration of antibiotics should not be delayed for diagnostic imaging in patients in whom bacterial meningitis is suspected.*

Subdural effusions should be treated with subdural paracentesis only when one suspects that the effusions are responsible for seizures or for prolonged fever as a result of subdural empyema. Paracentesis also may be useful if the effusion is responsible for symptoms of increased

intracranial pressure or is the cause of focal neurologic signs.[114,119] In most cases, subdural taps are not required.

Seizures should be carefully monitored particularly in patients with high bacterial counts in CSF (many organisms on Gram stain) but insufficient inflammation (few polymorphonuclear leukocytes in CSF) and, when noted, are treated expeditiously. A patent airway must be maintained, and appropriate anticonvulsants must be administered. Sodium phenobarbital (7 mg/kg loading dose) may be administered parenterally, followed by a maintenance dose of 5 mg/kg/day in two divided doses. If necessary, diazepam (≤0.2 mg/kg) or lorazepam (0.05 mg/kg/dose, 4 mg maximum) infused intravenously for 1 to 2 minutes may be used. If prolonged seizure control is needed, phenytoin (5 mg/kg/day) in two divided doses may be used. Phenytoin generally does not depress the respiratory center to the same extent as phenobarbital does, and it may benefit the patient by inhibiting the secretion of ADH. If the seizure activity no longer is apparent after the second hospital day and the patient has no focal neurologic signs at the time of discharge from the hospital, anticonvulsants may be discontinued. Phenytoin and phenobarbital can induce hepatic microsomal enzymes; their use may increase the metabolism rate of chloramphenicol and possibly cause a significant decrease in the serum concentration of this antibiotic if it has been used for treatment of meningitis.[288]

An electroencephalogram is indicated in patients with meningitis and seizures when focal seizures are noted, seizures persist more than 72 hours after presentation, seizures occur after the third day of hospitalization, a subdural effusion is noted, or prolonged alteration in sensorium is present. An electroencephalogram may be valuable in distinguishing abnormal intermittent posturing from movements associated with seizure activity.

Persistent fever (>8 or 9 days' duration) has been noted.[25] In the multicenter pneumococcal study, the mean duration of fever was 4.4 ± 3.9 days.[16] Suppurative complications, including subdural or pleural empyema, septic arthritis, and pericarditis, should be sought carefully. The rare occurrence of brain abscess in association with bacterial meningitis also may lead to persistent fever. Nosocomial intercurrent infection, usually viral, may cause prolonged fever in a child with meningitis. Complications of therapy, such as suppurative thrombophlebitis or a urinary tract infection after prolonged catheterization, are additional considerations. Persistent fever may be related to the severity of the infection. Poor therapeutic response (especially in multidrug-resistant organisms) occurs, and repeated lumbar puncture must be considered on an individual basis. Drug fever often is cited but rarely is the cause of persistent fever and remains a diagnosis of exclusion.

PROGNOSIS AND SEQUELAE

The prognosis in patients with bacterial meningitis depends on many factors: (1) the age of the patient, (2) the time course or progression of illness before antibiotic therapy is effective, (3) the specific microorganism causing the disease, (4) the number of organisms or the quantity of capsular polysaccharide material present in the meninges and CSF at the time of diagnosis, (5) the rapidity with which CSF is sterilized after initiation of antibiotic therapy, (6) the presence of disorders that may compromise host response to infection, and geographic location of the patient (low-income countries).[105,200,221,355]

The younger the patient and the greater the antigenic load at the time of admission, the worse the prognosis. Bacterial colony counts seem to be a more reliable indication of sequelae than is antigen concentration. Seizures, subdural effusions, bacteremia, and a more prolonged period of fever occur more frequently in children who have more than 10^7 CFU/mL of a particular organism in the CSF at the time of admission.[123] Children with colony counts equal to or greater than 10^7 CFU/mL also are significantly more likely to experience hearing loss and speech disturbance than children with meningitis but lower concentrations of bacteria within CSF specimens.[123] The concentration of TNF in serum has been associated with a fatal outcome in patients with meningococcal meningitis.[375] Elevated concentrations of IL-1β and TNF within the CSF of patients with bacterial meningitis also have been correlated significantly ($p < .002$) with a higher incidence of neurologic sequelae of disease.[260]

The mortality rate for bacterial meningitis in children who are beyond the neonatal period has been reduced to 1 to 5 percent. Although antibiotic therapy has reduced the mortality rate, up to 50 percent of the survivors of meningitis have some sequelae of disease.[102,105,119,144,347] Most studies from which estimates of sequelae have been derived have been retrospective, and the patients were enrolled for many years (1951-1968). Although antibiotic treatment of these individuals may have been relatively standardized during this period, ancillary methods employed in their care were not controlled.

Neurologic sequelae are common in survivors of meningitis and include hearing loss, cognitive impairment, and developmental delay.[105] For example, in 1991 the Metropolitan Atlanta Developmental Disabilities Surveillance Program identified bacterial meningitis as the leading postnatal cause of developmental disabilities, including cerebral palsy and mental retardation.[64] Hearing loss happens in 22 to 30 percent of survivors of pneumococcal meningitis compared with 1 to 8 percent after meningococcal meningitis.*

The frequency of complications of meningitis can be assessed most appropriately by prospective evaluation. In 1975, Sell[325] began a prospective study of 50 infants and children who recovered from *H. influenzae* meningitis. Fifty percent of this group were entirely normal, 9 percent were normal except for behavioral problems, and 28 percent had significant handicaps. The major handicaps noted included hearing loss (10% to 11%), language disorders or delayed language development (15%), impaired vision (2% to 4%), mental retardation (10% to 11%), motor abnormalities (3% to 7%), and seizures (2% to 8%).

Twenty-one postmeningitic children were paired with a sibling and tested by the Wechsler Intelligence Scale for Children. The mean IQ of the postmeningitic

*References 16, 101, 200, 362, 367, 376.

children was 86, and the mean IQ of control children was 97 (p <.05). Comparison of results for individual pairs revealed that 29 percent of postmeningitic children scored 1 full standard deviation below their siblings; no survivor had a score 1 standard deviation higher than a sibling.

Feldman and Michaels[121] reported that children who recovered from meningitis caused by *H. influenzae* and who were evaluated 10 to 12 years later maintained grades and scores comparable with those of their siblings as they progressed to middle school. Their academic success may require more school and family support to compensate for the minor differences in IQs that had been noted.

In 1995, Grimwood and colleagues[164] reported the results of a prospective cohort study of 158 meningitis survivors, 3 months to 14 years old, who were treated in a single center between 1983 and 1986. Between 1991 and 1993, 130 children (82% of the original cohort) were evaluated at a mean age of 8.4 years and a mean of 6.7 years after their meningitis. Results of blinded, audiologic, behavioral, neurologic, neuropsychologic, and sociodemographic assessments were compared with those of sex-matched and grade-matched control children. A systematic increase in the risk for abnormality or for poorer functioning was noted across all categories tested in children with meningitis versus control children. The differences reached statistical significance for tests of fine motor function, intelligence, neuropsychological function, school behavior, and auditory figure-ground differentiation.

Eleven children who had experienced meningitis (8.5% of the cohort studied) had major deficits (hydrocephalus, persistent seizures, spasticity, blindness, IQ <70, or profound hearing loss). Twenty-four (18.5%) of the survivors of meningitis and 14 (10.8%) of the control children had minor deficits (IQ of 70 to 80, inability to read, abnormalities in speech discrimination possibly referable to mild to moderate hearing loss, and school behavior problems). Overall, one in four of the children in this study had either a serious disabling sequela or a functionally important behavior disorder or neuropsychologic or auditory dysfunction that adversely affected academic performance.

This prospectively followed cohort was reevaluated 12 years post meningitis; impairment, although not severe, still persisted in the postmeningitic patients compared with controls.[14] After having meningitis, the children were "more than twice as likely as controls to require special educational assistance" and "took longer to complete tasks, made more errors, were less organized, and struggled within problem-solving situations." Decreased performance in language tasks and executive skills also were seen in children whose age was younger than 12 months at onset of meningitis.

A prospective study of bacterial meningitis in children revealed that 32.8 percent of children had abnormalities detectable on neurologic examination at the time of discharge, but by 5 years after discharge specific deficits were noted in only 11.1 percent of the total group. As a result of the onset of late seizures in some of these patients, the frequency of neurologic sequelae 15 years after discharge was 14 percent.[287] Specific complications or sequelae of meningitis in these patients are shown in Table 31-13. Shortly after discharge, hemiparesis or quadriparesis was noted in 30 patients (12.4% of the total group), but at 1 year after discharge, paralysis was noted in only 5 patients. These data reflect the tendency for even major neurologic defects to clear unpredictably with time. This important observation suggests the need to maintain cautious optimism in discussing long-term complications of meningitis with parents.

The mean IQ (±1 standard deviation) of the entire group of patients (235) after recovery was 94 (±23 standard deviations), with a range of 33 to 150. Twenty-nine children (17.3%) had IQs less than 80, and 22 (11.6%) had IQs less than 70. A comparison of these patients with their siblings and other control children revealed no significant difference in mean IQ. A significantly greater

proportion (p <.01) of children who recovered from meningitis had IQs less than 80 compared with children from control groups. These results differ from those of Sell.[325] Tejani and associates[356] also prospectively evaluated children who had recovered from bacterial meningitis using siblings as controls. They reported no significant differences in verbal performances or full-scale IQs between patients with meningitis and the sibling control population.

The prospective nature of these studies has permitted an assessment of factors that herald a poor prognosis and that may be discernible at or near the time of admission. Evidence of inappropriate secretion of ADH was correlated significantly (p <.01) with abnormal neurologic examinations at 3 months after discharge and with low IQs. The age of the child correlated inversely with the development of subdural effusion (p <.01), the occurrence of hearing deficits (p <.02), and low IQ (p <.05). The presence of focal neurologic findings in patients who were not postictal at the time of admission correlated significantly (p <.001) with abnormal neurologic examination, which was noted previously. Focal deficits indicating cerebral injury noted at admission or during the course of hospitalization were associated significantly (p <.001) with the development of late (1 to 15 years after discharge) afebrile seizures.[287] Focal neurologic findings at the time of admission proved to be a reliable predictor of permanent sequelae of bacterial meningitis. Focal deficits at admission also correlated significantly with low IQs (p <.001), even at 2 and 3 years after discharge from the hospital. The quantity of antigen in the initial CSF specimen and the number of organisms present also correlated significantly (p <.01) with sequelae of meningitis.[119] A prospective multicenter study of 180 children with pneumococcal meningitis between 1993 and 1996 revealed that 14 (7.7%) of 180 children died. No deaths were related to treatment failure by an antibiotic-resistant strain. Of the 166 surviving children, 41 (25%) developed motor defects and 48 (32%) of 151 children had moderate to severe unilateral or bilateral hearing loss. By CT or MRI of 103 patients, brain infarcts were noted in 39 (38%); subdural effusions in 25 (24%); hydrocephalus in 22 (21%); cerebritis in 12 (12%); and brain edema in 6 (6%).[16]

The outcome of patients with pneumococcal meningitis caused by penicillin-nonsusceptible or cefotaxime-nonsusceptible isolates has not differed from that caused by susceptible strains.[16,128,194] This finding is explained in part because vancomycin has been administered empirically to most children with suspected bacterial meningitis since the mid 1990s in the United States and in other parts of the world where treatment failures have been reported as a result of antibiotic-resistant *S. pneumoniae*.[274]

Meta-analysis of 90 published reports from 1980 to 2008 revealed that the most common types of major sequelae after bacterial meningitis were hearing loss (33.6%), followed by seizures (12.6%), motor deficit (11.6%), cognitive impairment (9.1%), hydrocephalus (7.1%), and visual disturbance (6.3%) (Table 31-14). The risk for at least one major sequela was almost three times greater in the World Health Organization African region (pooled risk estimate 25.1%) and southeast Asian region (21.6%) compared with the European region (9.4%).[105]

Other specific sequelae or complications of bacterial meningitis that have been observed include cranial nerve involvement, hemiparesis or quadriparesis, muscle hypertonia, ataxia, permanent seizure disorders, and development of obstructive hydrocephalus. Subdural effusions (as noted earlier) are so frequent in young children that they can be considered a part of the general disease process, rather than a persistent or troublesome complication of the meningeal infection. Development of brain abscess after bacterial meningitis is exceedingly rare[125]; when it is found, the possibility that it preceded the development of meningeal infection must be considered, and a careful search for other sites of infections such as endocarditis should be initiated.

Significant hearing loss after bacterial meningitis has been reported frequently. The mechanisms responsible for hearing deficits include spread of infection along the auditory canal and cochlear aqueduct, serous or purulent labyrinthitis, and, with time, replacement of the membranous labyrinth with fibrous tissue and new bone.[35,187,230,233,300] Damage to inner ear structures and subsequent hearing loss also is affected by the immune response of the host. TNF-α has been shown to produce cytolytic effects by the production of oxygen-free

TABLE 31-14 **Median Risk (%) of Sequelae After Bacterial Meningitis**

Sequelae	All Causes	*S. pneumoniae*	*H. influenzae*	*N. meningitidis*

From a review of 90 published papers from 1980 to 2008 (Edmond K, Clark A, Korczak VS, et al. Global and regional risk of disabling sequelae from bacterial meningitis: a systematic review and meta-analysis. *Lancet Infect Dis* 2010;**10**:317–28.)

radicals. Animal studies have shown a decreased incidence of hearing loss when animals are treated with antibody blockade of TNF-α[13] and scavenging of oxygen-free radicals by antioxidant therapy.[206]

Deafness generally is noted early in the course of bacterial meningitis and is independent of the therapy provided.[101,189,258,325,372] Ataxia has been reported as a presenting sign of bacterial meningitis in children with hearing loss noted at a later date.[191,324] Presumably, the insult to the vestibular and auditory systems occurred concomitantly in these children. The early loss of hearing noted by several investigators suggests that hearing loss is *not* associated specifically with the use of a particular antimicrobial agent. Early diagnosis and treatment apparently do not prevent the development of deafness in many children who develop hearing loss as a consequence of bacterial meningitis.

Estimates of the frequency of hearing loss in retrospective studies vary from 2.4 to 29 percent.[101,105] Overall, 48 of 151 (32%) of the children with pneumococcal meningitis in the multicenter study had unilateral or bilateral moderate to severe hearing loss.[16] Occasionally, hearing loss noted early may improve over weeks to months.[300]

No correlation has been found between hearing loss and either the age of the patient at the onset of meningitis or the duration of illness before admission.[101] A significant correlation was noted between hearing loss and the presence of seizures before admission, the duration of fever in the hospital after therapy has been initiated (which presumably reflects more severe disease), treatment with antibiotics administered orally before a definitive diagnosis of bacterial meningitis was established, and a depressed CSF-to-blood glucose ratio at the time of admission.[101,193] Koomen and associates[212] developed a nomogram to predict the probability of development of hearing loss using five factors: (1) duration of symptoms before admission, (2) absence of petechiae, (3) CSF glucose level, (4) infection by *S. pneumoniae*, and (5) ataxia; they were thus able to identify effectively patients at risk for developing hearing loss with excellent sensitivity (100%) using a cutoff of 0 on the point scale.

Because hearing deficits occur so commonly in patients with bacterial meningitis, hearing evaluation by evoked response audiometry in young, uncooperative children is recommended routinely at the time of or shortly after discharge from the hospital. Repeated audiometric evaluation is recommended after discharge if the results of the initial examination are abnormal. Pure tone audiometry can be used for older, cooperative children. Differentiation of hearing deficits resulting from conductive disturbances from deficits related to damage to the eighth cranial nerve is important. Some children who have repetitive episodes of otitis media may experience conductive loss that is unrelated to the meningitis.

Systematic review of neurocognitive impairment in children after CNS infection revealed deficits in cognition and motor function to be very common.[59,105] Koomen and associates[213] reported one third of Dutch children with non–*H. influenzae* type b meningitis were found on follow-up to have academic or behavior limitations or both. Childhood meningitis survivors also were found to have a higher incidence of nonspecific symptoms, such as headaches, and significantly more symptoms of inattention, hyperactivity, and impulsiveness compared with nearest-age siblings.[34]

Only one study assessed the value of the Pediatric Risk of Mortality (PRISM) score in predicting outcomes of bacterial meningitis.[239] This study was done in a subgroup of children requiring mechanical ventilation. The best predictor of death and functional states on follow-up evaluation was the PRISM score. When the score was less than 20 within the first 24 hours of admission to the pediatric intensive care unit, a favorable outcome was noted in 82 percent. When the score was 20 or higher, a favorable outcome was noted in only 30 percent ($p < .009$).

CT has revealed evidence of cerebral infarction in children who had a diagnosis of bacterial meningitis established within 1 or 2 days of the onset of symptoms of a febrile illness.[339] In most of these cases, abnormalities in cerebrovascular dynamics (arteritis, thrombosis, thrombophlebitis), ventricular dilation, or both have been observed.

PREVENTION

Pneumococcal Infection

Chemoprophylaxis

Antibiotic chemoprophylaxis of children exposed to pneumococcal meningitis is not recommended regardless of immunization status.[10] In asplenic patients (functional and anatomic), daily chemoprophylaxis against pneumococcal infection is recommended with oral penicillin therapy.[10] The reader is referred to the CDC and AAP statements for the details of these recommendations.

Immunoprophylaxis

In a large randomized trial,[42] more than 37,000 infants received either the 7-valent pneumococcal conjugate vaccine (PCV7) containing polysaccharides of serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F conjugated to CRM_{197} or meningococcal serogroup C oligosaccharide conjugated to the same protein. Vaccines were administered at 2, 4, 6, and 12 to 15 months of age. The PCV7 was found to be 97.4 percent efficacious in preventing acquisition of invasive pneumococcal infections caused by vaccine serotype isolates. As a result of this study, in 2000, the PCV7 was recommended by the ACIP and the AAP Committee on Infectious Diseases for all children younger than 24 months of age to prevent invasive pneumococcal infections.[9,67]

In February 2010, a 13-valent pneumococcal conjugate vaccine (PCV13, Prevnar 13) was licensed by the FDA for prevention of invasive pneumococcal diseases caused by the 13 pneumococcal serotypes covered by the vaccine (PCV7 serotypes plus 1, 3, 5, 6A, 7F, and 19A) and for prevention of otitis media caused by serotypes in PCV7.[70,72] PCV13 is approved for use among children aged 6 weeks to 71 months and has replaced PCV7. Use of PCV13 is recommended by the ACIP for routine vaccination for all children aged 2 to 59 months, vaccination of children aged 60 to 71 months with underlying

medical conditions that increase their risk for pneumococcal disease or complications (e.g., chronic heart disease, chronic lung disease, diabetes mellitus, CSF leaks, cochlear implant, functional or anatomic asplenia, human immunodeficiency virus infection, chronic renal failure and nephrotic syndrome, diseases associated with treatment with immunosuppressive drugs or radiation therapy, congenital immunodeficiency), and children who previously received one or more doses of PCV7.[70,72]

Meningococcal Infection

Chemoprophylaxis

Chemoprophylaxis is recommended to all household members of a patient with meningococcal meningitis and in daycare and nursery school contacts, preferably within 24 hours of the diagnosis of the primary care.[12] Prophylaxis may be provided for individuals who had contact with the patient's oral secretions through kissing or sharing toothbrushes or eating utensils during the 7 days before onset of disease in the index child. Prophylaxis is not recommended routinely for health care personnel unless they have had close exposure through mouth-to-mouth resuscitation, intubation, or suctioning before antibiotic therapy was initiated. Schoolroom classmates and hospital contacts of patients usually are not given prophylactic treatment.

Minocycline and rifampin have proved to be 80 to 90 percent effective in eradicating carriage of meningococci.[169] Both drugs are secreted in the saliva in concentrations greater than the MICs for meningococci. The use of minocycline has been accompanied by frequent and significant vestibular reactions, even after a single dose of 100 mg, and generally should not be used.[60-62,388]

Rifampin is the drug of choice in most instances and can be used in a dose of 600 mg twice daily for four doses in adults and in doses of 10 mg/kg/dose twice daily for four doses in children 1 to 12 years of age. A dose of 5 mg/kg every 12 hours for four doses can be used in children 3 months to 1 year of age.[257] The emergence of rifampin-resistant strains in treated meningococcal carriers has been reported to occur with a frequency of 0 to 27 percent.[91,106,383]

A single intramuscular dose of ceftriaxone has proved to be an effective alternative to rifampin for prophylaxis in meningococcal contacts.[323] This approach to prophylaxis may be particularly useful in circumstances in which compliance with the use of oral rifampin is considered questionable. The efficacy of ceftriaxone has been confirmed for only group A strains, but its effect is likely to be similar for other serogroups. Ceftriaxone has the advantage of easier dosage and administration and safety in pregnancy.[12] Ceftriaxone may be given intramuscularly in a dose of 125 mg for individuals younger than 12 years old and in a dose of 250 mg for individuals 12 years and older.

Ciprofloxacin given to adults in a single oral dose of 500 mg has been effective in eradicating meningococcal carriage.[12] Ciprofloxacin presently is not recommended for individuals younger than 18 years old or for pregnant women.

Immunoprophylaxis

Because secondary cases may occur several weeks or more after onset of disease in the index case, meningococcal vaccine may be used as an adjunct to chemoprophylaxis when an outbreak is caused by a serogroup contained in the vaccine. The CDC has outlined recommendations for the administration of the meningococcal serogroup C vaccine to control outbreaks.[65]

A serogroup-specific quadrivalent polysaccharide meningococcal vaccine against group A, C, Y, and W135 *N. meningitidis* is approved for use in the United States in children 2 years old and older. The vaccine consists of 50 μg each of the respective purified bacterial polysaccharides. It may be given subcutaneously as a single 0.5-mL dose and can be given concurrently with other vaccines.

The FDA approved a quadrivalent meningococcal conjugate vaccine (MenACWY-D, Menactra) in January 2005 and a quadrivalent meningococcal conjugate vaccine (MenACWY-CRM, Menveo) in February 2010.[69,71] Because of the conjugate vaccine's ability to induce a T-cell–dependent immune response and subsequently longer immunologic memory compared with polysaccharide vaccines, it is advantageous. Both vaccines include serotypes A, C, Y, and W-135 and were initially licensed for use for persons aged 11 to 55 years. The ACIP recommended that persons aged 2 through 55 years at increased risk for meningococcal diseases and all adolescents aged 11 through 18 years be immunized with meningococcal conjugate vaccine.

As of January 2011, the FDA lowered the approval age range for use of both vaccines to include persons aged 2 through 55 years. MenACWY-D is also licensed as a two-dose series for children aged 9 through 23 months (see later). The ACIP recommended vaccination with meningococcal conjugate vaccine for children aged 2 through 10 years at increased risk for meningococcal disease. A two-dose primary series is recommended for children with terminal complement deficiencies (e.g., C5-C9, properdin, factor H, or factor D deficiencies) or anatomic or functional asplenia. A single primary dose is recommended for children with increased risk for disease if they are travelers to or residents of countries in which meningococcal disease is hyperendemic or epidemic (e.g., the meningococcal belt of sub-Saharan Africa). No meningococcal vaccine is recommended in children aged 2 through 10 years with no increased risk for meningococcal disease. The ACIP also recommended a single booster dose of meningococcal conjugate vaccine for adolescents who received a previous dose before age 16 years. For persons aged 2 through 55 years at increased risk for meningococcal disease (i.e., persons with asplenia or terminal complement deficiencies or laboratory workers who work with *N. meningitidis*), a booster dose is recommended if they remain at increased risk.

In April 2011, the FDA approved the use of MenACWY-D as a two-dose primary series for children aged 9 months through 23 months at high risk for invasive meningococcal disease (Table 31-15).[71]

Similar to other conjugate vaccines, meningococcal C conjugate vaccines are more immunogenic than the pure

TABLE 31-15 **Summary of MenACWY-D Recommendation for Children Aged 9 Months Through 23 Months at High Risk for Invasive Meningococcal Disease**

Risk Group	Primary Series	Booster Dose
Children aged 9 through 23 months at high risk for invasive meningococcal disease (except children with functional or anatomic asplenia)*	Two doses, 3 months apart Catch-up dose if the second is not received on schedule: at the earliest opportunity	Initial booster 3 years after completing the primary series if person remains at increased risk Continued boosters at 5-year intervals after the initial booster if person remains at increased risk
Children at high risk for invasive meningococcal disease with functional or anatomic asplenia	Two doses, 2 months apart, beginning at age 2 years and ≥4 weeks after completion of PCV13 vaccine series	Initial booster 3 years after completing the primary series if person remains at increased risk Continued boosters at 5-year intervals after the initial booster if person remains at increased risk

*Children who have persistent complement component deficiencies (e.g., C5-C9, properdin, factor H, or factor D), children who are traveling to or residents of countries where meningococcal disease is hyperendemic or epidemic, and children who are in a defined risk group during a community or institutional outbreak.

polysaccharide vaccine in infants younger than 2 years of age.[237] Because of a high incidence of meningococcal disease in the United Kingdom, a meningococcal serogroup C-CRM_{197} was administered in a phased program beginning in November 1999 to all children younger than 18 years of age.[295] Surveillance studies to assess short-term efficacy have shown a 97 percent efficacy for teenagers and a 92 percent efficacy for toddlers in the prevention of meningococcal serogroup C infection.

An effective serogroup B meningococcal vaccine has not been produced to date. The polysaccharide capsule cross reacts with fetal neural tissues, causing autoantibodies. Different strategies have been tried to develop a safe vaccine against serogroup B meningococcus, including use of outer membrane proteins (OMP) and lipopolysaccharide components. Reverse vaccinology was used to develop a serogroup B meningococcal vaccine using the genome from the strain MC58,[22] which resulted in a vaccine formulation of the five genome-derived neisserial antigens (GNAs) with factor H binding protein (GNA1870), neisserial adhesin A (NadA or GNA1994), neisserial heparin-binding antigen (GNA2132), GNA2091, and GNA1030. This vaccine (Bexsero) has been shown to induce immune responses for all age groups including infants and offers broader coverage of serogroup B meningococcal isolates; results from additional phase III trials are pending.[22]

Haemophilus influenzae Meningitis

Chemoprophylaxis

The most comprehensive study concerning the spread of *H. influenzae* type b infection among household contacts was coordinated by the CDC.[378] Data collected from 19 states were analyzed prospectively. *H. influenzae* meningitis was reported in 1403 patients. Eighty-two percent of exposed families were investigated for the occurrence of *H. influenzae* disease within 30 days of its onset in the index patient. Systemic disease caused by *H. influenzae* type b developed in 9 of 1687 contacts (0.5%) who were younger than age 6 years. The risk for infection in patients younger than age 4 years was 2.1 percent; the risk in children younger than age 1 year was 6 percent. The risk for secondary infection of household contacts in the 30 days after onset of meningitis in the index case was 585 times greater than the age-adjusted risk in the general population and was similar to the risk for secondary meningococcal disease in household contacts. This nationwide study provided an important impetus for finding a chemoprophylactic regimen that could prevent secondary infection in household contacts.

A nationwide, collaborative, placebo-controlled trial was conducted subsequently among household (children <6 years old) and daycare center contacts of individuals with invasive *H. influenzae* type b disease.[28] Four of 765 placebo-treated contacts experienced secondary disease versus none of 1112 rifampin-treated contacts ($p = .027$).

The AAP Committee on Infectious Diseases recommends that rifampin be provided orally once a day for 4 days in a dose of 20 mg/kg (maximum dose 600 mg/day) to all household contacts (children and adults) regardless of age in households with at least one unvaccinated contact younger than 4 years.[11] The dose for infants younger than 1 month is not established, but it may be reduced to 10 mg/kg. Rifampin prophylaxis is not required, however, when all of the household contacts younger than 4 years have been fully immunized. All members of households with a fully immunized but immunocompromised child, regardless of age, should receive rifampin because of concern that the immunization may not have been effective.

When two or more cases of invasive disease have occurred within 60 days and unimmunized or incompletely immunized children attend a daycare facility, rifampin should be administered to all personnel and attendees. When a single case has been reported, the use of rifampin is controversial, and many experts recommend *no* prophylaxis.[11] Unimmunized or incompletely immunized children should receive a dose of vaccine and should be scheduled for completion of the recommended age-specific immunization schedule.

No data document the safety of rifampin administered during pregnancy. Prophylaxis with rifampin is not

recommended for pregnant women who are contacts of infected infants.

Patients receiving rifampin should be advised routinely that their urine, sweat, and tears will be stained orange. Individuals should be advised to refrain from using contact lenses while receiving rifampin therapy because the lenses may be stained permanently.

Immunoprophylaxis

The incidence of *H. influenzae* type b invasive disease and meningitis decreased dramatically after the introduction of vaccines that initially were found to be effective at 15 months of age[8] and then later found to be effective at 2 months of age.[321] Currently, three conjugate vaccines are approved for infants beginning at 2 months of age: HbOC, PRP-OMP, and PRP conjugated to tetanus toxoid (PRP-T). The ACIP and the AAP recommend universal infant immunization with HbOC or PRP-T at 2.4 and 6 months of age or PRP-OMP at 2 and 4 months of age.[19,63]

Passive immunization of infants also has been studied with use of bacterial polysaccharide immunoglobulin.[313] This preparation given in a single intramuscular dose of 0.5 mL/kg provides significant protection for infants from *H. influenzae* type b disease for 3 or 4 months.

CHAPTER 32

Parameningeal Infections

Xavier Sáez-Llorens • Javier Nieto Guevara

BRAIN ABSCESS

Although it is uncommon, pediatric brain abscess remains a serious, life-threatening neurologic problem. Those with congenital heart disease, an ongoing infection, or an immunocompromised state are particularly at risk. The symptoms on presentation may include those associated with a space-occupying lesion in the brain, and neuroimaging has made the diagnosis of brain abscess more reliable. Abscess formation may occur in the parenchyma of the central nervous system, in the subdural space, or in the epidural space. It can originate from contiguous site infections (e.g., skull osteomyelitis, chronic otitis),[46] from underlying vascular anomalies (e.g., congenital cyanotic heart disease), after head trauma or neurosurgical procedures, or from cryptogenic sources. These conditions can alter neurologic function by direct destruction of nervous tissue, by infarction after inflammatory occlusion of veins and arteries, or by compression caused by mass effect.

Advances in diagnostic and therapeutic modalities since the 1990s have improved the prognosis of this serious disease. The mortality rate associated with brain abscesses seems to be decreasing. This reduction probably is the result of the advent of head imaging and its use to guide precise location and management, improvement in surgical techniques, and advances in antibiotic development. Goodkin and coworkers[18] identified 54 patients aged 5 days to 34 years of age who were diagnosed with a brain abscess at the Boston Children's Hospital from 1945 to 1980 and 1981 to 2000. They found a reduction in the number of abscesses that occurred in the setting of sinus or middle ear infection (26% vs. 11%, respectively) and an increase in the number of children who were treated with antibiotics alone (1% vs. 22%). These investigators did not observe, however, any additional decline in the mortality rates in their institution between 1981 and 2000. Fischer and associates[16] found a reduction in mortality rate from 36 percent before 1970 to 14 percent after 1970. Tekkok and Erbengi[50] described a similar decline, from 30 percent in the era before the use of computed tomography (CT) to 3 to 6 percent in the last 5 years of their study and zero in the last 3 years of their study. Other case series also have reported a mortality rate of zero.[27]

Although the mortality rate seems to be decreasing, a significant percentage of children continue to have residual neurologic deficits, including epilepsy, permanent motor or sensory dysfunction, visual field defects, and personality changes.[16,20,23] Some children also require placement of a ventriculoperitoneal shunt.[11]

Pathogenesis and Pathology

Brain abscess is a focal, intracerebral infection that begins as a localized area of cerebritis and eventually ends in a collection of pus surrounded by a well-vascularized capsule.[1] For practical purposes, brain abscesses usually are classified according to the likely entry point of the infection (Table 32-1). Ear and mastoid infections are associated with formation of an abscess at the temporal or cerebellar locations; sinus and dental infections give rise to purulent collections in the frontal lobe; and metastatic spread from distant foci in children with congenital cardiac or pulmonary right-to-left shunts commonly results in involvement of any parenchymal area, including parietal or occipital regions.[26,46]

The most common origin of microbial infection in children remains direct or indirect cranial infection arising from the middle ear, paranasal sinuses, or teeth. Seeding of the brain presumably occurs via transit of infecting microbes through the valves and emissary veins that serve these regions. A direct erosion of skull and dura by osteomyelitis-induced sinus or middle ear infection can be another mechanism of bacterial spread.[8] Resulting abscesses tend to be solitary and superficial. Metastatic inoculation of the brain from distant extracranial sources (pulmonary infection, endocarditis) tends to provoke multiple cerebral abscesses, with a distribution that reflects the regional cerebral blood flow of the area affected, usually the middle cerebral artery network.[8]

In children with cyanotic congenital heart disease, bacteria are not filtered out by the pulmonary vascular bed, which allows for systemic spread.[11] This situation rarely occurs in patients younger than age 2 years, and the abscess or abscesses usually are in areas of brain perfused by the middle cerebral arteries. Evidence of associated endocarditis is rare in these cases, although acute bacterial endocarditis may be complicated by septic infarction of the brain and abscess formation.[41]

Formation of an abscess by direct bacterial implantation may complicate compound skull fractures, scalp wounds, anterior cranial fossa or temporal bone fractures, and chronic cerebrospinal fluid (CSF) fistula. Abscesses also rarely may develop during the course of bacterial meningitis.[45] Despite identification of all these potential routes, 20 to 30 percent of cases are classified as cryptic brain abscess for which no obvious predisposing factor can be identified.

The brain is remarkably resistant to microbial infection. Despite the common occurrence of occult bacteremia in infants and children, cerebral abscess is a quite rare

TABLE 32-1 **Primary Source, Usual Location of Lesion, and Associated Neurologic Findings in Children with Brain Abscess**

Primary Source	Location of Abscess	Associated Neurologic Findings
Sinusitis	Frontal lobe	Headache, behavioral changes, motor/speech disorders, depressed consciousness, forced grasping and sucking, hemiparesis
Chronic otitis/mastoiditis	Temporal lobe	Dyspraxia and aphasia (dominant hemisphere), ipsilateral third cranial nerve palsy, ipsilateral headache, upper homonymous hemianopsia, motor dysfunction of face and arm
	Cerebellum	Dizziness, vomiting, ipsilateral ataxia and tremor, sixth cranial nerve palsy, nystagmus (toward lesion)
Dental infection	Frontal lobe	
Head trauma	Related to injured site	Variable by region involved
Postoperative	At operative site	Variable by region involved
Metastatic spread	Multiple lesions	Variable by region involved
	If parietal lobe involved	Visual field defects in inferior quadrant, homonymous hemianopsia, dysphasia (dominant hemisphere), dyspraxia, and contralateral spatial neglect (no dominant hemisphere)

disease. This resistance is attributable in part to the abundant blood supply of the brain and the relative impermeable blood-brain barrier.[1] Although certain underlying brain morbidities, such as previous stroke, intracerebral hematoma, or underlying neoplasm, may serve as a nidus of abscess formation in adults, affected children have no apparent predisposing brain lesion. In animal models of infection, induction of abscess usually requires direct inoculation of numerous organisms into the animal's cerebrum.[35]

Experimental animal studies and use of CT have provided evidence of the clinical evolution of a brain abscess.[2] In the early stage of cerebritis (days 1 to 3), a focal area of acute inflammation, vascular dilation, microthrombosis, rupture of small vessels, and edema is present. The center of the lesion then undergoes liquefaction. Expansion of the cerebritis and formation of a necrotic central focus are seen in the late cerebritis stage (days 4 to 9). Establishment of a ring-enhancing dense collagenous capsule of well-vascularized tissue with peripheral gliosis or fibrosis or both occurs at the early capsule stage (days 10 to 14). Finally, during the late capsule stage (>14 days), host defenses act to wall off the abscess, and a well-developed capsule results.

Death can occur if the volume of pus and surrounding edema induce a significant increase of intracranial pressure leading to brain herniation. In addition, cerebral abscesses can rupture into the ventricular system or through the cortex into the subarachnoid space, resulting in acute deterioration and a life-threatening event.[11] Figure 32-1 shows the gross appearance of a well-defined abscess of hematogenous origin. Various microscopic features are illustrated in Figures 32-2 through 32-4.

The spectrum of microorganisms cultured from brain abscesses has changed with time. This change reflects improved microbiologic isolation techniques, early and aggressive treatment of primary infections, and better neurosurgical procedures. In more recent series, the predominance of *Staphylococcus aureus* has decreased and identification of anaerobes has increased.[7,14,54]

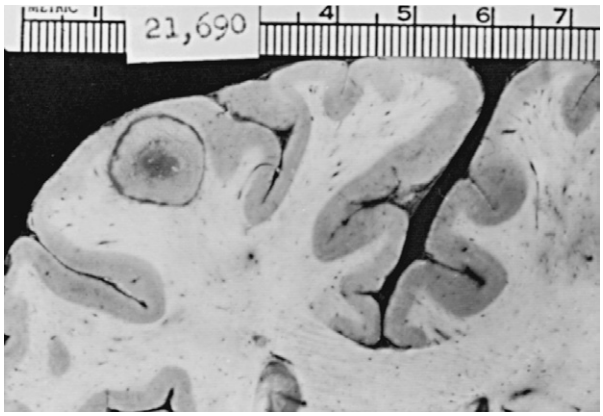

FIGURE 32-1 ■ Circumscribed cerebral abscess of hematogenous origin.

Anaerobic bacteria isolated from brain abscesses include species of *Bacteroides*, *Peptostreptococcus*, *Fusobacterium*, *Veillonella*, *Propionibacterium*, *Prevotella*, and *Actinomyces*. Aerobic and microaerophilic streptococci, staphylococci, *Haemophilus* spp., gram-negative enteric bacilli, and *Pseudomonas aeruginosa* also are implicated frequently. In children with impaired host defenses, fungal etiology (*Candida*, *Aspergillus*, *Cryptococcus*, *Histoplasma*, *Coccidioides*, and *Mucor* spp.) or uncommon pathogens, such as *Toxoplasma*, *Nocardia*, *Mycobacterium*, and *Listeria* spp., can be identified.[16] Parasites such as amebae, *Cysticercus*, *Schistosoma*, or *Paragonimus* are very rare causative pathogens.[35] *Citrobacter koseri (diversus)* and *Enterobacter sakazakii* are particularly able to cause brain abscesses in neonates.

In order of etiologic importance, the predominant organisms causing brain abscess in children are aerobic and anaerobic streptococci (60% to 70% of cases), gram-negative anaerobic bacilli (20% to 40%), Enterobacteriaceae (20% to 30%), *S. aureus* (10% to 15%), and fungi (1% to 5%).* Multiple aerobic and anaerobic organisms

*References 3, 4, 6, 7, 14, 16, 26, 35, 38, 46, 54.

are isolated in approximately one third of patients, especially in patients with chronic otitis. No growth is reported from 30 percent of properly handled purulent specimens. A reasonable speculation of the likely causative microbes can be made according to the predisposing source of infection (Table 32-2).

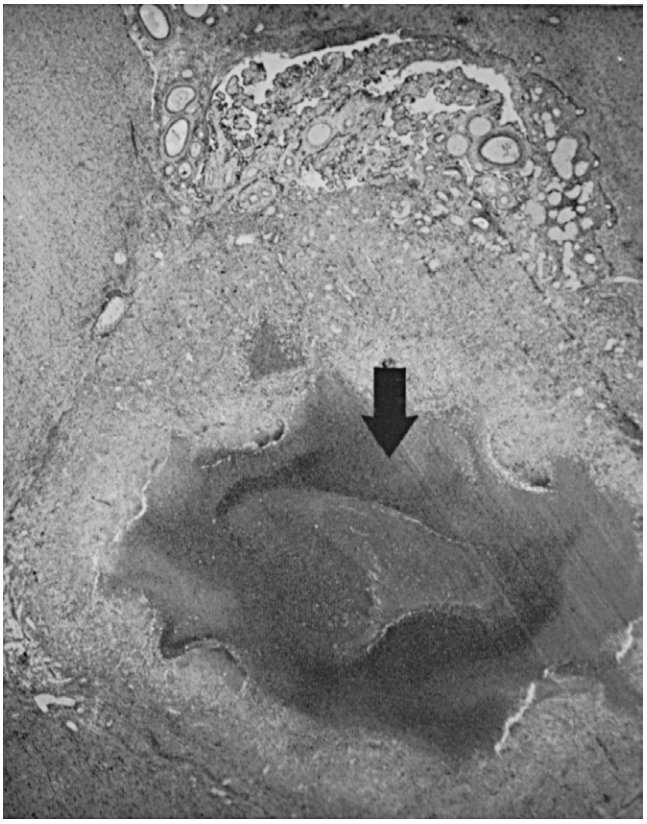

FIGURE 32-2 ■ Area of necrosis and liquefaction in a cerebral abscess *(arrow)*.

Clinical Manifestations

The clinical presentation of a brain abscess depends on the size of the collection, its location, the multiplicity of lesions, the host's immune status, and the age of the patient. Generally, symptoms and signs can be related to the effect of a space-occupying mass, to the focal neuronal dysfunction of the parenchymal region involved (see Table 32-1), or to accompanying clinical findings of the underlying predisposing infection. Because on early evaluation most children with cerebral abscess present with vague or nonspecific signs and symptoms, the physician must have a high index of suspicion to recognize the condition as early as possible (Table 32-3). When a patient develops significant alterations in mental status, the prognosis is most ominous.[11,46]

In older children and adolescents, headache is the most common initial symptom. Irritability occurs more commonly in infants and small children. The nature of the headache has no particular distinguishing features and usually is poorly localized. Sudden worsening of a preexisting headache can indicate rupture of the brain abscess into the ventricular space, which has a poor prognosis.[9]

Fever is usually a nonspecific symptom at some phase in the illness in about 50% of patients; and, overall, it may be found in up to 80% of children.[36] Drowsiness, confusion, and vomiting occur frequently during the acute phase of disease. Lethargy, stupor, and coma usually are later events and potentially associated with adverse outcome. Papilledema is present in less than one fourth of the cases, but its presence requires immediate neurosurgical assessment and CT.

Focal neurologic disturbances reflect the location of the abscess and can be detected in 30 to 50 percent of cases on presentation (see Tables 32-1 and 32-3).[55] Frontal location is characterized by development of motor speech disorders, memory deficits, personality changes, and

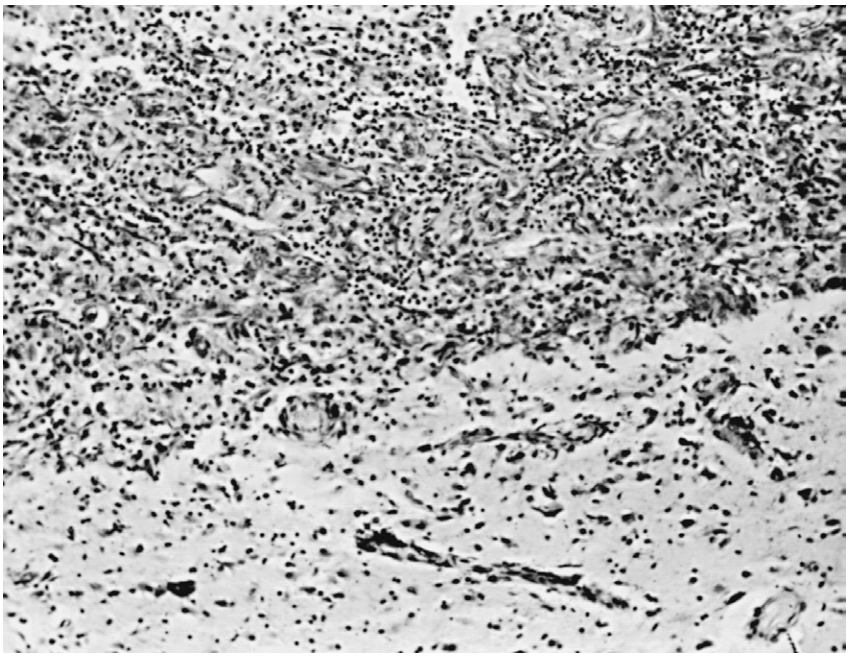

FIGURE 32-3 ■ Astroglia and fibroblasts forming the capsule of a cerebral abscess.

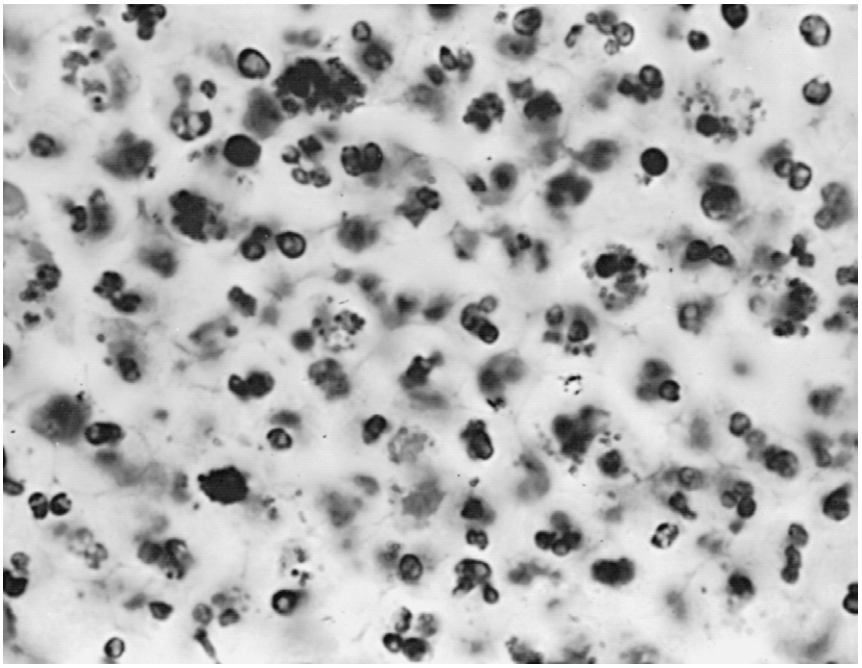

FIGURE 32-4 ■ Mononuclear and polymorphonuclear leukocytes are in the center of a cerebral abscess.

TABLE 32-2 **Primary Source, Usual Etiologic Pathogens, and Recommended Empirical Antibiotic Therapy in Children with Brain Abscess**

Primary Source	Usual Etiologic Microorganisms	Recommended Empirical Antibiotic Combination
Upper respiratory tract infection		
Sinusitis/dental infection	Viridans and anaerobic streptococci, *Haemophilus* spp., *Fusobacterium* spp., *Bacteroides* spp. (non-*fragilis*)	Penicillin or cefotaxime/ceftriaxone + metronidazole or ampicillin + chloramphenicol or sulbactam
Chronic otitis/mastoiditis	Aerobic and anaerobic streptococci, gram-negative enteric bacilli, *Bacteroides* spp. (including *B. fragilis*), *Pseudomonas aeruginosa*	Penicillin + metronidazole + ceftazidime
Head trauma	*Staphylococcus aureus,* aerobic streptococci, gram-negative enteric bacilli	Oxacillin/nafcillin (vancomycin) + cefotaxime/ceftriaxone
Postoperative	*Staphylococcus epidermidis, S. aureus,* gram-negative rods, *P. aeruginosa*	Vancomycin + ceftazidime
Metastatic spread		
Endocarditis	*S. aureus,* viridans streptococci	Oxacillin/nafcillin (vancomycin) + cefotaxime/ceftriaxone + metronidazole
Pulmonary infection	Aerobic streptococci, *Actinomyces, Fusobacterium*	Oxacillin/nafcillin (vancomycin) + cefotaxime/ceftriaxone + metronidazole
Congenital heart disease	Viridans streptococci, *Haemophilus* spp., *Haemophilus aphrophilus*	Cefotaxime/ceftriaxone + metronidazole or ampicillin + chloramphenicol or sulbactam
Bacterial meningitis	*Streptococcus pneumoniae, Haemophilus influenzae* type b, *Salmonella* spp., *Citrobacter* (neonates)	Cefotaxime/ceftriaxone ± vancomycin (resistant pneumococcal strains)
Cryptogenic source and immunosuppression*	Any type of microorganisms *Nocardia,* fungi, *Mycobacterium tuberculosis*	Oxacillin/nafcillin (vancomycin) + ceftazidime + metronidazole Oxacillin/nafcillin (vancomycin) + ceftazidime + metronidazole

*In areas with significant prevalence of methicillin-resistant staphylococcal strains or penicillin allergy, immunosuppressed children should be treated with broad coverage and with consideration of amphotericin B therapy. Antituberculous therapy should be considered for children with exposure to tuberculosis. Antibiotic regimens are likely to vary by geographic location based on resistant organisms.

TABLE 32-3 **Frequency of Presenting Signs and Symptoms in Children with Brain Abscess**

Symptoms	%	Signs	%
Headache	60-70	Focal neurologic deficits	35-50
Fever	50-80	Papilledema	30-40
Vomiting	35-55	Meningeal signs	25-35
Seizures	30-45	Hemiparesis	20-30
Mental changes	30-40	Nerve palsy	10-20
Coma	15-20	Ataxia	5-15

depressed consciousness. Hemiparesis occurs with lesions in the postfrontal region or as a consequence of uncal herniation. Abscess in the temporal lobe is characterized by a contralateral homonymous upper quadranopia. If the dominant hemisphere is affected, nominal dysphasia and aphasia are characteristic symptoms. Patients with cerebellar abscesses classically exhibit dizziness, nystagmus, defective conjugate eye movements, ataxia, tremor, and hypotonia. Seizures occur in at least 30 to 45 percent of patients, may be focal or generalized, and may occur at any time during the course of the disease. If the parietal region is involved, visual field defects, homonymous hemianopsia, dysphasia, and dyspraxia can be present.

The rapidity with which symptoms develop can vary substantially. Most patients are symptomatic within 1 week of the onset of formation of an abscess. Immunocompromised children can have a more insidious progression of clinical findings. The presentation of brain abscess in infancy can be suspected by bulging fontanelle, vomiting, irritability, and an enlarging head circumference. Seizures occur commonly, particularly in small infants, and at any time during the course of the disease.[14] School-aged children with cyanotic congenital heart disease, notably tetralogy of Fallot or transposition of the great vessels, also can exhibit symptoms and signs related to their chronic cardiac disease.

Rupture of Brain Abscess into the Ventricular System

Rupture of an abscess into the ventricle with consequent ventricular empyema is a dreaded complication because the mortality rate is greater than 50 percent, and residual neurologic deficits, including hydrocephalus, are the rule in patients who survive. Frequently, rupture occurs before the diagnosis of abscess has been established and surgical removal can occur. A sudden worsening in the patient's clinical state heralds this event. High fever, shock, meningismus, and altered consciousness are prominent clinical signs.

Rupture of the abscess into the ventricle is seen more frequently in patients with deep-seated abscesses or in immunocompromised patients.[49] Although a modest pleocytosis and elevated protein concentration in CSF may have been identified earlier, 50,000 to 100,000 polymorphonuclear leukocytes per microliter and markedly reduced glucose concentration in the CSF are usual findings. Organisms may be seen on smear of the CSF and cultured from the fluid. In other words, the patient has developed purulent meningitis, and treatment must include high doses of antibiotics and surgery (see Treatment).

The concurrence of abscess and meningitis in the past has led to the assumption that brain abscess can be a complication of meningitis; this rarely, if ever, is the case, although meningitis may develop during the incipient stages of abscess formation after intracranial invasion of organisms from a contiguous extracranial source. In such circumstances, the abscess may seem to be a consequence of the leptomeningitis. Given a potential source of infection in the ear or paranasal sinuses, the clinician must be wary and appreciate the possibility of this sequence of events. Abscess has been reported to complicate *Citrobacter* meningitis in infants, but careful pathologic study has shown vasculitis and liquefaction necrosis of the white matter without capsule formation.[54]

Laboratory Diagnosis

Laboratory tests frequently are not helpful in supporting the clinical diagnosis of brain abscess.[11,34,46] Children usually have unremarkable leukocyte counts, and the erythrocyte sedimentation rate can be normal. Blood cultures rarely are positive. Performance of a lumbar puncture is potentially dangerous because it can be associated with brain stem herniation.[10] In addition, CSF analysis uncommonly provides useful clinical information. Usual CSF findings include an elevated protein, mild mononuclear pleocytosis, and hypoglycorrhachia. CSF cultures usually are negative, unless the abscess has drained into the ventricular system or has been a complication of meningitis.

Culturing abscess material obtained at the time of surgical drainage provides the best opportunity to make a microbiologic diagnosis. Proper handling and processing, with attention given to optimal anaerobic and aerobic isolation techniques, can identify the causative organism in most cases, especially when antimicrobial therapy has not been instituted previously.[35] The high incidence of sterile cultures reported in the literature is probably because of the inadequacy of bacteriological procedures. Under such conditions, sterile cultures may reach even unjustified rates higher than 32.2 or 40 percent.[39]

Diagnosis

Magnetic resonance imaging (MRI) is used at an increasing rate in evaluation of cerebral abscess both at the time of diagnosis and in follow-up. Similar MRI findings can be observed in infarction, demyelinating disorders, and neoplastic processes. Diffusion-weighted MRI and magnetic resonance spectroscopy have been shown to be effective methods in differentiating cerebral abscesses from tumors.[6,35] Figure 32-5 illustrates the appearance on MRI of a right frontal cerebral abscess in a 10-year-old girl. CT remains an excellent alternative, however, if MRI is unavailable (Fig. 32-6). Intravenous administration of contrast material is advised because the abscess may be missed otherwise.[13,24] Serial CT or MRI

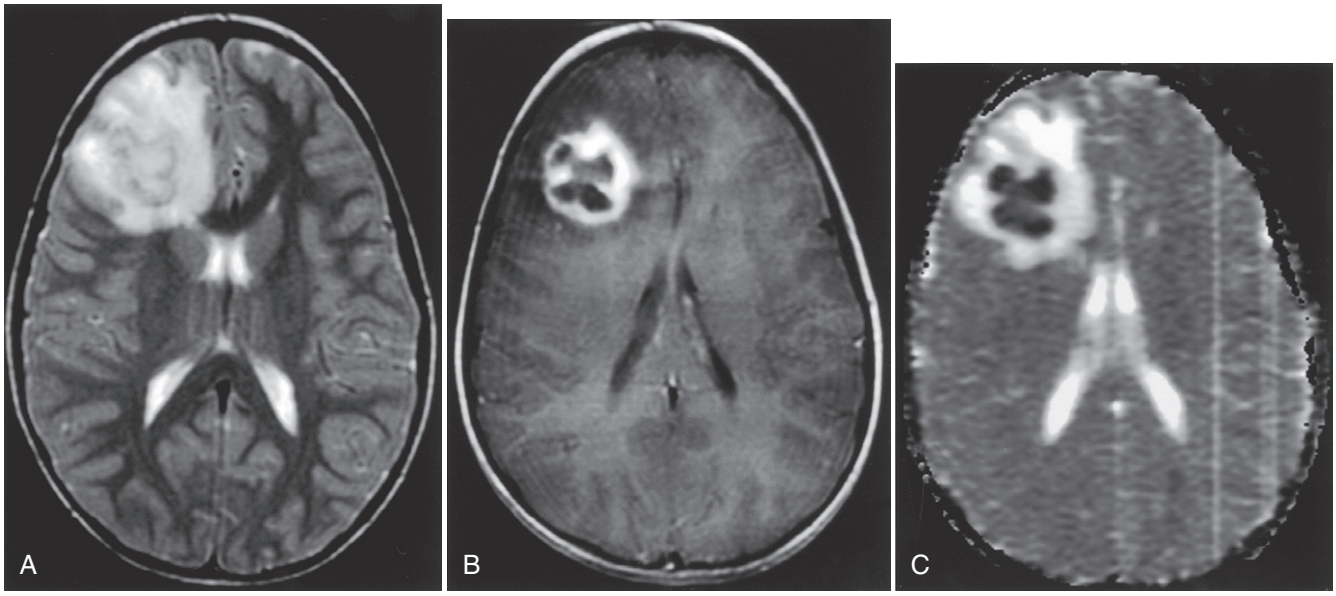

FIGURE 32-5 ■ Bacterial abscess in a 10-year-old girl. **A,** Axial T2-weighted MR image shows an irregular mass in the right frontal lobe with a hypointense wall and surrounding vasogenic edema. **B,** Gadolinium-enhanced T1-weighted MR image shows intense, smooth enhancement of the capsule. **C,** Apparent diffusion coefficient map from a line-scan, diffusion-weighted study shows decreased signal within the cavity, compatible with restricted diffusion and suggesting an abscess cavity rather than tumor necrosis. (Courtesy Kim F, MD, Northwestern University School of Medicine, Chicago.)

performed weekly or biweekly provides evaluation of the response to therapy and of the need for repeating the surgical procedure. MRI is more accurate than is CT for establishing the diagnosis of cerebritis, cerebellar abscess, edema formation, and brain stem purulent collections.[19,22] On T1-weighted sequences, brain abscesses appear hypointense and show ring enhancement after administration of intravenous gadolinium. In contrast, on T2-weighted images, the typical mature abscess has a hyperintense central area of pus surrounded by a well-defined hypointense capsule and surrounding edema.

Because specific images allow precise lesion staging, this information provides important clues for the surgeon to suspect the likelihood of encountering purulent material of a well-developed abscess at the moment of drainage. The presence of gas within the abscess cavity on head imaging suggests communication of the abscess with air outside the skull, although gas-forming bacteria in the abscess cavity rarely may be responsible.[33]

Plain skull films generally are normal in children with brain abscess. In small infants, separation of cranial sutures indicates intracranial hypertension. Radionuclide brain scan, arteriography, and ventriculography have been replaced largely by CT and MRI for the diagnosis of brain abscess. Indium-labeled leukocyte scans and thallium-brain single photon emission computed tomography (SPECT) to differentiate brain abscess from tumor in questionable cases have not been studied adequately in the pediatric population, but these methods seem promising in affected adults.[44]

Abnormalities on electroencephalography may be localized and can help in excluding a more generalized, bilateral intracranial disease, such as encephalitis. Unilateral slow waves (delta, 1 to 3/sec) characterize the usual

FIGURE 32-6 ■ Contrast-enhanced CT scan shows a ring-enhancing left frontal cerebral abscess *(arrows)* in a 3-week-old boy with concurrent *Enterobacter* meningitis. electroencephalographic findings in cases of cerebral abscess.

After the diagnosis of brain abscess has been established, a careful search should be made for a source of infection serving as a site of origin for hematogenous spread or direct inoculation of organisms into the central nervous system. In addition to obtaining data from the history and physical examination, the physician should extend the MRI or CT evaluation to include the mastoids and paranasal sinuses. An echocardiogram should be obtained to assess for concurrent endocarditis. Other testing should be guided by the history and physical examination findings.

Treatment

No prospective clinical trials have compared various surgical and medical treatment strategies available to guide the management of cerebral abscesses in children. Most surgical and medical treatment guidelines are based on populations consisting primarily of adult patients. Appropriate management of brain abscesses apparently requires a combined surgical and medical approach,[30] with isolated medical management limited to patients who are neurologically intact and in whom the abscess is in the cerebritis stage[21] or the abscess or abscesses are small,[43] or to patients who are too unstable to undergo a surgical procedure.

The initial treatment of solitary and multiple brain abscesses relies on the aspiration of the cavity contents followed by the initiation of empirical antibiotic coverage while the cultures are processing. CT- or MRI-guided stereotactic aspiration is accurate, minimally invasive, and associated with few complications.[17] Mamelak and colleagues[32] suggested performing head imaging biweekly or on any sign of clinical deterioration, with further aspiration if the cavity enlarges or fails to diminish after 3 to 4 weeks. Because excisions may be associated with increased risk for developing neurologic sequelae, surgery should be reserved for patients who do not respond to the strategy of repeated aspiration and medical management and when an abscess results in a significant mass effect. Madhugiri and colleagues[31] evaluated 231 children who underwent treatment for focal intradural abscess/empyema at the National Institute of Mental Health and Neurosciences, Bangalore in India. These included 57 children with cerebral abscess, 65 with supratentorial empyema, 82 with cerebellar abscess, and 27 with infratentorial empyema. All patients underwent emergency surgery (which was either bur hole and aspiration of the lesion or craniotomy/craniectomy and excision/evacuation), along with antibiotic therapy, typically 2 weeks of intravenous and 4 weeks of oral therapy. The antibiotic regimen was empirical to begin with and was altered based on the antimicrobial susceptibilities of the causative organism(s) when isolated. Hydrocephalus was managed with external ventricular drainage initially and with ventriculoperitoneal shunt if warranted. Mortality rates were 4.8 percent for cerebral abscess, 9.6 percent for cerebellar abscess, 10.8 percent for supratentorial subdural empyema, and 3.7 percent for posterior fossa subdural empyema. The choice of surgery was found to have a strong bearing on the recurrence rates and outcome in most groups, with aggressive surgery with craniotomy leading to excellent outcomes with a low incidence of residual/recurrent lesions.

Although results of cultures are pending, the selection of antibiotics should be guided by the primary source of infection, pertinent patient history, and results of microscopic examination of the pus (see Table 32-3). Meropenem monotherapy can be considered as treatment in cerebral abscess.[33] The appropriate duration of antimicrobial therapy for brain abscess is unclear. A 6- to 8-week course of parenteral antibiotics has been recommended traditionally, provided that the etiologic organisms are susceptible and adequate surgical drainage is achieved.[34] In selected cases with uncomplicated infection and complete surgical removal of a well-delineated abscess, shorter courses of treatment (3 to 4 weeks) are likely to be sufficient.[47] Nonetheless, many authorities recommend 2 to 3 months of additional oral antimicrobial therapy to prevent relapses.[11] Some guidelines recommend switching to oral antibiotics after 2 weeks if the culture was positive and continued the same for 4 weeks. The reasons for the switch to oral antibiotics after 2 weeks are mainly logistical and economic because patients in developing countries find it difficult to stay in hospital (far away from their homes) for 6 weeks.[31] In fungal, nocardial, and helminthic infection, surgical intervention frequently is required because of failure of medical treatment. Surgical procedures can be used to reduce increased intracranial pressure, obtain pus for microbiologic diagnosis, and enhance the antibiotic efficacy. In carefully selected patients (illness duration ≤2 weeks, neurologically intact, no signs of increased intracranial pressure, and abscess ≤3 cm in diameter), medical therapy alone can be successful.

With the advent of head imaging and the current methods of treatment employing head imaging, an overall reduction in the mortality rate has occurred; however, a high proportion of children with cerebral abscesses develop neurologic deficits. Eradication of potential sources of infection before the abscess has developed is logical preventive medicine. Early diagnosis and treatment are imperative and can be facilitated by the liberal use of MRI or CT when this diagnosis is even a remote consideration.

Antibiotic therapy, emergency surgery, and management of associated complications are the mainstays of treatment of these lesions.

ADJUNCTIVE AGENTS

The use of corticosteroids for treatment of brain abscess is controversial. These agents usually are indicated to control life-threatening intracranial hypertension that is associated with risk for herniation or when significant symptoms and signs are presumed to be the result of cerebral edema. Severe brain edema may necessitate the additional administration of intravenous mannitol. Corticosteroids interfere with the inflammatory response,

retard the encapsulation process, increase development of necrosis, potentially reduce antibiotic concentrations inside the purulent collection, and alter CT images.[42]

Anticonvulsants are recommended in children who have developed seizures potentially to prevent further episodes. Duration of anticonvulsant therapy should be individualized and guided by an electroencephalographic study in the follow-up phase of disease. Most authors recommend providing at least 3 months of prophylaxis if no more seizures have occurred.[11]

SUBDURAL EMPYEMA

Subdural empyema is defined as a collection of pus in the preformed space between the cranial dura mater and arachnoid mater, while epidural abscess is produced by suppurative infection in the potential epidural space.[51]

Pyogenic infection in the subdural space is designated as subdural empyema or sometimes, but less correctly, as subdural abscess. The sources of infection and microorganisms responsible are the same as those encountered in brain abscess. It is a rare disease; only one case was seen at St. Louis Children's Hospital during a period when 122 patients with bacterial meningitis and 3 patients with cerebral abscess were treated. The primary source of subdural empyema in this single case was not found, which increasingly is true for the pediatric experience. Farmer and Wise[15] and Jacobson and Farmer[25] found associated meningitis in six of eight infants with subdural empyema (seen over a 16-year period), suggesting that the latter was a complication of the former. We also have encountered this situation, albeit rarely, and the subdural fluid usually is turbid, rather than frankly purulent.

In older children, the infection apparently does not follow leptomeningitis. Although leptomeningitis may complicate subdural empyema, infections of the paranasal sinuses and mastoid region, usually chronic, spread to the subdural space directly because of osteomyelitis or by way of infected veins that penetrate the skull. Extension to cortical veins and to major venous sinuses frequently is associated with subdural empyema, as discussed elsewhere in this section. Why in some cases the infection is restricted to one or another anatomic site or sites (e.g., epidural space, subdural space, parenchyma of the brain, or blood vessels) is unknown. Subdural empyema may be hematogenous in origin. It is an infrequent but recognized complication of intracranial surgery. The anatomy of the subdural space is such that the infection often extends widely over one or both cerebral hemispheres, and accumulation of pus in the parafalcine region occurs commonly.

Clinical Manifestations

The symptoms and signs of the primary source of infection may be prominent, subtle, or absent. Increasingly severe headache, high fever, signs of meningeal irritation, and progressive neurologic deficits referable to the site of the lesion are reported in the typical untreated case. Focal or generalized seizures are prominent, especially in cases of cortical injury from associated vasculitis. Signs of increased intracranial pressure become prominent as the mass of pus enlarges. In infants, a fullness of fontanelle, vomiting, and depressed responsiveness are seen. Transillumination of the skull can be positive. Older children also may develop papilledema. As the intracranial pressure increases, symptoms and signs progress, ultimately leading to temporal lobe or cerebellar herniation and the characteristic syndromes of these complications.

Diagnosis

The laboratory findings reflect the active infectious process. Peripheral leukocytosis and a predominance of polymorphonuclear leukocytes with immature cells frequently are seen. The CSF in infants reflects the common association with leptomeningitis, and the findings depend on when the fluid is examined. Before the meningitis has been treated adequately, organisms may be cultured; the glucose concentration may be low, and the protein concentration high in the CSF. Later, the CSF findings are the same as those for treated meningitis, but viable organisms can be recovered from the subdural collections when the CSF is sterile. Specific antigens may be shown in subdural collections by tests such as latex agglutination in the absence of viable organisms. In older children, the characteristic CSF findings include elevated pressure with a few to a few hundred or more leukocytes per microliter, with polymorphonuclear leukocytes predominating. The protein concentration frequently is elevated, the glucose concentration is normal, and the fluid is sterile.

In the past 2 or more decades, subdural empyema in children has become more difficult to diagnose clinically because of antimicrobial therapy. When initiated early, antimicrobial therapy may attenuate the dramatic nature of the disease, especially the symptoms and signs of acute infection. Because the diagnosis of subdural empyema often is confused with that of brain abscess, radiographic studies are necessary to establish the correct diagnosis. CT may be the most cost-effective imaging modality in epidural abscess and subdural empyema because of its accessibility and sensitivity.[5] CT scans can appear normal in up to 50% of the patients; therefore, a high index of suspicion is required, coupled with subtle CT scan clues, including minimal midline shift, cortical enhancement, and edema in the adjacent cerebral hemisphere.[40] The use of thin-slice coronal CT scans may help to reduce uncertainty in diagnosis.[37] In our series, the initial CT scan revealed negative findings in 10 cases, which led to delayed diagnosis (Fig. 32-7).

MRI, if available in the acute setting, may be the imaging modality of choice because it provides a better anatomic delineation of any collections that may be present than does CT, and it can adequately display areas of localized meningeal infection.[10] The use of MRI, however, must be weighed against the need for urgent diagnosis and intervention for patients in extremis (Fig. 32-8).

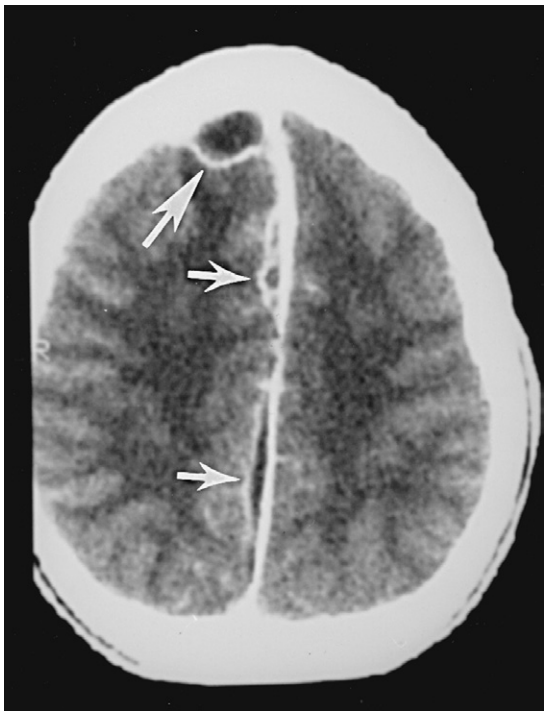

FIGURE 32-8 ■ Contrast-enhanced CT scan shows a right frontal epidural abscess *(large arrow)* concurrent with an interhemispheric subdural abscess *(small arrows)* in a 13-year-old boy who developed headache, fever, and vomiting after fracture of the right frontal sinus. (Courtesy Robson CD, MD, Harvard Medical School, Boston, Mass., and Barnes PD, MD, Stanford University School of Medicine, Stanford, Calif.)

Treatment

Until a causative organism is identified, the patient should receive broad-spectrum antibiotics intravenously in dosages appropriate for bacterial meningitis. After the offending organism is identified, the sensitivities of that organism to specific medications dictate selection of more precise antibiotic therapy. In infants, antibiotic therapy may be sufficient when the fluid is cloudy only, but if thick, purulent material is obtained by subdural paracentesis or, in older children, if the clinical and radiographic evidence indicates a subdural empyema, surgery is requisite. Depending on individual circumstances, craniotomy or multiple bur holes with irrigation of the subdural space should be accomplished.

Mortality and morbidity rates are high (20% to 40%) in most series but lower in some.[48,56] Early diagnosis and treatment are imperative. The early use of CT seems to be responsible for improved therapeutic results.[56]

EPIDURAL ABSCESS

Because the dura mater is adherent to the inner aspect of the cranium, epidural abscesses rarely attain a large size, and they consequently do not exert significant pressure on the brain. They are important because they can serve as a focus for spread of infection into the subdural space, leptomeninges, or brain. The infection may involve local penetrating vessels and lead to their occlusion, with extension to venous sinuses and other vessels. Infection of the middle ear, mastoid bone, or ancillary air sinuses may lead to epidural abscess, as in the case of subdural empyema and brain abscess. Often, epidural abscess coexists with the other lesions and presumably develops first. Osteomyelitis may be evident, which usually is the case with mastoiditis and often is evident after head injury with comminuted fracture of the skull or after intracranial surgery. A case of an adolescent boy with osteomyelitis and epidural abscess complicating a wrestling injury has been reported.[52]

Local pain, tenderness, and fever may be the only signs. Treatment usually includes antibiotics and surgery in the presence of osteomyelitis. Exclusion of associated intracranial infections is mandatory; the epidural infection serves to raise these diagnostic possibilities.

SPINAL EPIDURAL INFECTIONS

Spinal epidural infections may be acute or chronic, and they may be restricted in their extent or extend longitudinally over many segments of the spinal cord because the epidural space offers no resisting structures. Most often, the process affects the posterior region of the spine, with maximal pus or granulomatous tissue found over the dorsal aspect of the cord or spinal roots. In Danner and Hartman's[12] series from the New York Hospital, however, in approximately half of the patients, the pus primarily was anterior to the cord. In spinal osteomyelitis, the pus may be more viscous ventrally. Occasionally, the purulent material may encircle the neural

elements. In infants and children, this condition is rare; no case was encountered at the St. Louis Children's Hospital during the 39 months in which 122 cases of bacterial meningitis were seen. In an extensive report by Baker and colleagues[4] covering a 27-year period at the Massachusetts General Hospital, only 6 of 39 patients were younger than 20 years of age, and the youngest was 11 years old. The incidence ranged from 0.2 to 1.2 hospital admissions each year. In approximately half of the patients in this series, acute purulent material was discovered at operation or autopsy, with *S. aureus* incriminated in more than half of the cases. In the remainder, a granulomatous process was found, associated with a wide variety of bacteria. No instance of tuberculous infection occurred, although in many regions of the world this organism remains an important consideration. Nonbacterial infective agents may include fungi or parasites.

The neural dysfunction probably results from direct compression of the spinal cord, roots, and nerves, but impaired circulation from associated inflammation and occlusion of vessels is at least a contributory factor in some cases. Determining with certainty the extent to which each of the previous mechanisms contributes to neural dysfunction often is difficult. Extensive necrosis of the cord may result in advanced cases in which a prompt diagnosis has not been made.

Sources of Infection

In tuberculous and other chronic infections, osteomyelitis and intervertebral disk infection are common occurrences, but adults primarily are affected. Acute spinal epidural infections usually occur after hematogenous spread from furuncles, pharyngitis, dental abscesses, decubitus ulcers, and urinary tract and wound infections.[28] They may complicate spinal surgery, and lumbar puncture rarely has been implicated as a source.[6] Osteomyelitis seldom occurs. The patient may have a history of minor trauma to the back. Presumably, trauma results in local tissue injury or hemorrhage, forming a nidus for the developing infection.

Clinical Manifestations

Fever is the rule, and the temperature is higher in patients with acute infections. Patients appear septic, and toxic delirium occurs frequently. Heusner,[21] in his classic article dealing primarily with acute epidural abscesses, divided the clinical phases as follows: (1) spinal ache, (2) root pain, (3) weakness, and (4) paralysis. Although certain therapeutic implications render this separation a useful way to consider the disorder, phases 3 and 4 are combined in the following discussion. That the various stages often overlap is axiomatic.

Phase 1: Spinal Ache

Spinal ache was a universal finding in Heusner's experience.[21] In a report from Baker and associates,[4] all 39 patients had backache of various degrees of severity. Local tenderness was absent in only 2 of their patients and should be searched for by carefully tapping over the spine.

Phase 2: Root Pain

Root pain is characteristic and is an early symptom that may assist in localization of the pathologic process. Root pain especially is prominent with lumbosacral disease in which roots are implicated without involvement of the spinal cord. The diagnosis is suspected infrequently until functional motor and sensory losses occur, which is unfortunate because therapy is most effective during the early stages. Progression to symptoms and signs of spinal cord involvement usually occurs within a few days except when the process is granulomatous, in which case the course tends to be prolonged, extending over several or more weeks.

Phases 3 and 4: Weakness and Paralysis

After weakness and impaired sensation referable to disease of the spinal cord appear, the progression to paralysis can be rapid, and immediate surgical treatment is imperative to maximize the likelihood of reasonable functional recovery. Even appropriate therapy at this stage often is ineffective, however, in restoring normal neurologic functions. Death occurs in at least 20 percent of cases; this rate has not changed significantly since 1948, despite the availability of a wide range of antibiotic agents.

Diagnosis

The value of MRI in the diagnosis and differential diagnosis of pediatric spinal infection is well established.[29] Diagnostic MRI findings of spinal infection include bone marrow edema, destruction of the affected vertebrae, abnormal signal intensity of the contiguous disc, and paraspinal or epidural extension of infection (Fig. 32-9). Epidural and paravertebral soft tissue changes on short-term follow-up MRI correlated better with patients' clinical symptoms compared with bone and disc destruction. Bone and disc changes can appear to progress more so than soft tissue infection despite adequate clinical response to therapy. Although MRI is essential for initial diagnosis, serial routine follow-up MR images were not necessary for the vast majority of cases. Wang and colleagues[53] examined 35 whole-spine and 16 localized spinal scans from 17 patients (age 2 months to 16 years, 9F:8M) who had 51 follow-up imaging studies done 2 weeks to 4.75 years after baseline. Seven children (41%) younger than 3 years of age underwent 33 follow-ups (65%); most required general anesthesia or conscious sedation. Short-term follow-up scans demonstrated epidural and/or paraspinal soft tissue changes correlating with clinical status and laboratory findings in all cases. However, MRI showed that bone and/or disk abnormalities continued and progressed in some cases despite clinical improvement.[53]

Follow-up MRI is not needed for patients with good clinical response; these patients should be observed

FIGURE 32-9 ■ Gadolinium-enhanced, sagittal, T1-weighted MR image shows a rim-enhancing lumbar spinal epidural abscess *(arrows)* in a 15-year-old boy with a 3-week history of lower back pain, followed by rapidly progressing left leg numbness and decreased bowel and bladder function. *Staphylococcus aureus* was cultured from purulent fluid removed after L4-L5 laminectomy was performed. (Courtesy Robson CD, MD, Harvard Medical School, Boston, Mass., and Barnes PD, MD, Stanford University School of Medicine, Stanford, Calif.)

clinically and/or have laboratory markers of inflammation tested. The segment of the pediatric population that might benefit from follow-up MRI includes those whose condition deteriorates clinically and those too young for a clinical response to be accurately assessed. If follow-up MRI is indicated, a localized spine scan rather than a whole-spine scan is recommended unless disease extension beyond the original focus is suggested. After epidural abscess is discovered, immediate neurosurgical intervention is necessary to prevent long-term neurologic sequelae. At the time of surgery, stains and cultures for aerobic and anaerobic bacteria, mycobacteria, and fungi should be obtained. If lumbar puncture is attempted when epidural abscess is suspected, the spinal needle (with stylet) is advanced slowly into the lumbar region, with periodic removal of the stylet and with suction applied gently *before* the thecal sac is entered.

If purulent material is obtained, the diagnosis is established, and the pus must be examined by a Gram-stained smear and cultured on various media under aerobic and anaerobic conditions. The leptomeninges should not be penetrated if purulent material is encountered; otherwise, CSF should be obtained. Characteristically, the CSF is clear or slightly opalescent and yellow if there is a block. Pleocytosis with a few too many hundred cells (with lymphocytes predominating) reflects a contiguous infectious process, but in the absence of meningitis no organisms can be identified and the CSF glucose concentration should be normal. The protein concentration always is elevated, and the level may be very high (several hundred to 2000 mg/dL) in the case of a partial or total manometric block.

The differential diagnosis includes myelitis caused by bacterial meningitis, syphilis, viruses, and a parainfectious process and by the syndrome of acute transverse myelopathy of unknown cause. Spinal ache is most prominent in acute transverse myelopathy, but, as a general rule, the entire illness is compressed in time, with paresis or paralysis evolving over the course of hours or a few days from the onset of disease. Impaired circulation of CSF does not occur in this or the aforementioned disorders. Rarely, a lymphoma may mimic a spinal epidural abscess. Spinal cord tumors, vascular malformations, and arachnoiditis are considerations when the course of disease is prolonged and evidence of sepsis is minimal or absent, as occurs with chronic epidural infections.

Treatment

Owing to variable etiology, identification of the responsible microorganism through neurosurgical drainage followed by long-term intravenous antibiotics remains the mainstay in treating extra-axial CNS infections. Optimal outcome is achieved with early diagnosis and therapy. Initial empirical antibiotic coverage is similar to that for brain abscess, although antifungal therapy need not be included, unless cultures or stains are positive for fungi. Treatment typically should be continued for 3 to 4 weeks, but it should be prolonged for twice this period if the patient has osteomyelitis. Despite advances, the morbidity and mortality rates for spinal epidural abscess remain high. One third of children with the disease die, and another third are left with permanent neurologic sequelae, including weakness, incontinence, and sensory abnormalities. Rapid diagnosis and treatment are essential to ensure a successful outcome.

CHAPTER 33

Fungal Meningitis

José R. Romero • Richard F. Jacobs

Fungi are rare causes of meningitis in children. *Candida albicans*, *Cryptococcus neoformans*, and *Coccidioides immitis* are the isolates found most commonly in pediatric patients. Making a diagnosis can be difficult. Fungal meningitis frequently is chronic, and patients may have few symptoms. The lack of obvious meningeal signs and symptoms and the uncommon incidence of a fungal cause often delay establishing the diagnosis. Inherent problems with the diagnosis of fungal infections of the central nervous system (CNS) begin with the basic microbiology of the organisms. Their fastidious growth, the prolonged time needed for culture, and the requirement of special media can render making a diagnosis of meningitis difficult.

Because cultivating many fungi from the cerebrospinal fluid (CSF) frequently is difficult, the use of serologic tests for antibodies and antigens helps define the infection more quickly and with more sensitivity. These tests can be done on CSF, serum, and, in some instances, urine.[168] For most infections, lipid formulations of amphotericin B have become the drug of choice, although its supremacy is being tested by some of the newer triazoles. CNS disease caused by fungi generally has high morbidity and mortality rates.

EPIDEMIOLOGY

The epidemiology of fungal meningitis depends on many factors. The geographic location of the patient or travel to an endemic area can be an important clue to defining the cause of the infection. The geographic distribution of fungal meningitis varies in the United States and worldwide. Histoplasmosis generally occurs in endemic areas of the Mississippi River valley.[167] Coccidioidomycosis occurs in the San Joaquin Valley and the desert Southwest of the United States and in Mexico.[3,112] Cryptococcosis distribution is worldwide, rather than in discrete endemic areas, but it seems to be associated with pigeon droppings and nesting areas of other birds.[93] Blastomycosis has a sporadic pattern of infectivity but generally occurs in states bordering the Mississippi and Ohio River basins, with occasional outbreaks occurring in the Great Lakes region and Canada.[44,79,138] *Candida* spp., *Aspergillus* spp., *Sporothrix schenckii*, and other fungal pathogens generally are not defined by geographic boundaries but depend more on environmental exposures and the immunocompetence of the individual. Uncommon species of yeasts and fungi, including *Rhodotorula rubra*, *Aureobasidium mansoni*, *Clavispora lusitaniae*, and *Bipolaris spicifera*, have been reported in nosocomial cases of meningitis.[64,85]

Many fungal infections (particularly infections caused by *Histoplasma* and *Candida* spp.) do not usually cause meningitis, unless the host is immunocompromised. The number of cases of cryptococcal meningitis has increased dramatically in association with the acquired immunodeficiency syndrome (AIDS) epidemic. A review from the mid-1980s by the Centers for Disease Control and Prevention showed an incidence rate of 6.8 percent for cryptococcal meningitis in patients with AIDS; however, the rate in pediatric patients with AIDS was 10 times lower (0.6%).[136] In the pre-AIDS era, patients known to be at risk for acquiring disseminated cryptococcosis included patients with lymphoma, patients on high-dose corticosteroid therapy, and patients with underlying cellular immune dysfunction.[19] Risk factors for developing *Candida* meningitis are similar to those for candidemia and include prolonged antimicrobial therapy, indwelling venous or ventricular catheters, hyperalimentation, corticosteroid use, recent neurosurgery or intra-abdominal surgery, and intravenous drug abuse.[109,132,150] Pediatric cases occur most commonly in neonates, particularly in newborns with very low birth-weight.[8,52,66,69,143] Of neonates with candidemia, 5 to 9 percent have associated meningitis.[26]

Inhalation is the most common means by which many fungi infect the host. Other fungi can be inoculated directly into the skin; this inoculation can occur in the outdoor environment or in the hospital setting (e.g., intravenous catheters), especially in infants with very low birth-weight.[8]

CLINICAL MANIFESTATIONS

Infections caused by *Candida* spp. in newborns with very low birth-weight can be particularly difficult to diagnose because of the broad range of symptoms. Most infants with disseminated candidiasis with meningitis present with respiratory distress and a supplemental oxygen requirement, and most progress to require mechanical ventilation.[8] *Candida* usually is identified in endotracheal washings, urine, and blood in patients with *Candida* meningitis, but infants have symptoms on average 11 days before the diagnosis is made. Ophthalmologic examinations may be very important in identifying disseminated *Candida* infections.[23] A careful funduscopic examination also can help determine whether increased intracranial pressure is present with papilledema. Marked

abdominal distention also occurs commonly in disseminated *Candida* infections in infants with very low birthweight and frequently is associated with guaiac-positive stools. Most patients also have temperature instability, elevated white blood cell counts, and feeding intolerance. Hepatomegaly may indicate the presence of systemic infection.

Physical manifestations diagnostic for other causes of fungal meningitis (e.g., *Cryptococcus*, *Blastomyces*, and *Histoplasma*) rarely are found because the infections usually are chronic. Looking carefully for other manifestations of fungal infections, especially the presence of skin lesions, is very important. All superficial lesions, nodules, and draining abscesses should be investigated because they may give a clue to the cause of subacute and chronic infections (e.g., *Coccidioides*, *Blastomyces*, and *Cryptococcus*).[58] Fungal stains, including India ink, should be performed on all biopsy specimens and drainage material, and all specimens should be processed for culture. Bone involvement is a common occurrence with certain fungal infections (e.g., *Cryptococcus* and *Blastomyces*).

The significance of isolating a fungus from CSF cannot be overemphasized. The finding of fungal organisms should be considered a true infection, and appropriate antifungal therapy should be initiated. A single CSF culture for *Candida*, in an otherwise immunocompetent host, or an unlikely meningeal pathogen *(Paecilomyces)* with an otherwise normal CSF should lead the physician to consider the possibility of contamination.[5] Repeat CSF cultures should be sought in such patients.

Infection with Specific Organisms

Candidal Meningitis

Candidal meningitis is rare in children. Arisoy and associates[5] reported that 2 percent of all positive CSF cultures were fungal organisms but *Candida* spp. accounted for 94.5 percent of the fungal isolates, including 9 of 23 newborn patients, 8 of whom were infants with very low birth-weight. Risk factors for positive CSF fungal cultures from neonates included antimicrobial therapy, umbilical catheterization, total parenteral nutrition, intubation, and prematurity.[37,38] In many cases of candiasis in neonates, concurrent meningitis exists but is not discovered until the time of autopsy.[26] Risk factors in children beyond the neonatal period included concurrent bacterial infection, chronic systemic or CNS disease, and the presence of central venous catheters. Histopathology models in animals have revealed hyphal invasion, vasculitis, abscesses, and acute and chronic inflammatory infiltration of meninges and brain parenchyma.[68]

Children with human immunodeficiency virus (HIV) infection are at risk for acquiring disseminated *Candida* infections, including meningitis.[90] In one study, 27 percent of HIV-infected patients with disseminated *Candida* infections had CNS involvement.[90] Nearly all HIV-infected patients who develop *Candida* infection do so as a result of nosocomial infection. Predisposing factors include oral candidiasis, central venous catheters, prolonged antibiotic therapy, and total parenteral nutrition. In HIV-infected patients, neutropenia is not a major risk factor. Simultaneous pulmonary disease, particularly viral, bacterial, or *Pneumocystis jiroveci* pneumonias, exists in most HIV-infected patients with disseminated *Candida* infection. Most patients are febrile for more than 14 days, with peak temperatures greater than 39° C (102.2° F) before the diagnosis is established. Recently, a homozygous mutation in *CARD9* has been associated with chronic mucocutaneous candidiasis and meningitis.[50] *CARD9* is an intracellular adapter molecule that receives signals from several antifungal pattern-recognition receptors.

The incidence of infection with *Candida* spp. other than *C. albicans* has increased dramatically in immunocompromised children, particularly children with malignancies. In a case series of children with leukemia, *Candida tropicalis* meningitis was uniformly fatal.[41] In addition to patients with malignancies and HIV infections, other children at risk for developing infection have been reported, including a child with myeloperoxidase deficiency.[95]

Development of resistance in *Candida* spp. is a concern. Intensive efforts to develop standardized, reproducible, and clinically relevant susceptibility testing methods for the fungi have resulted in the development of the standardized methodology for antifungal susceptibility testing of yeasts for the azole agents.[128] Isolates of *Candida glabrata* and *Candida krusei* with increasing resistance to amphotericin B have been described.[165] *C. lusitaniae* has shown intrinsic resistance to amphotericin B, and meningitis in an adult patient with a resistant strain has been reported.[133] *C. krusei* has been noted to have near uniform azole resistance, particularly in immunocompromised patients receiving suppressive azole therapy. Patients with meningitis caused by *C. glabrata* or any *Candida* spp. who are slow to clear infection, or in whom unexpected relapse occurs, should have antifungal susceptibility testing performed on their isolate.[114]

Candida meningitis usually responds to therapy with intravenous amphotericin B alone or in combination with oral flucytosine. The use of flucytosine is controversial; however, most reports support its use in meningitis. Flucytosine has been difficult to use in infants with low birth-weight because of the immaturity of their gastrointestinal tracts and the risk for developing necrotizing enterocolitis, as well as the lack of an intravenous formulation in the United States. Amphotericin B alone for systemic candidiasis, including meningitis, in neonates has been used successfully in patients who could not tolerate oral medication.[18] The most important factor in successful treatment is the initiation of therapy *quickly*, as soon as systemic *Candida* infection is suspected and frequently before the organism is isolated. Prolonged delays in initiating therapy result in high mortality rates.

Amphotericin B for children and neonates should begin at the desired 1 mg/kg daily dose and not be preceded by smaller test doses, because of the importance of early and effective therapy in improving outcome. In nonneonatal patients, a lipid formulation of amphotericin B can be used. Flucytosine can be used in nonneonatal patients at a dose of 150 mg/kg/day, divided every 6 hours. The use of flucytosine often requires careful monitoring and adjustment of the dosage based on serum

determinations. Flucytosine is not recommended for neonates.

Large, controlled trials using the azoles and newer agents for *Candida* meningitis are lacking. Huttova and coworkers[63] reported eight neonates with candidal meningitis treated with intravenous fluconazole with and without amphotericin B. Numbers from the study were too small to make conclusive recommendations. However, because of rapid clearance and differences in the volume of distribution of fluconazole in neonates, infants, and children, daily fluconazole doses in pediatric patients need to be doubled (12 mg/kg daily),[114] and more recent studies suggest a fluconazole loading dose in neonates of 25 mg/kg.[122] Lipid formulations of amphotericin B increasingly are preferred in adults, and liposomal amphotericin B was used successfully in five of six cases of *Candida* meningitis in newborns.[134] Optimal dosing is unknown, but many physicians prescribe liposomal amphotericin B or amphotericin B lipid complex at a dose of 5 mg/kg daily. Marr and associates[98] reported on the use of fluconazole plus flucytosine for the treatment of *Candida* meningitis in an infant with a very low birthweight. Voriconazole has excellent penetration of the CNS and is active against most *Candida* isolates causing CNS infections; however, the clinical experience with voriconazole is too limited to recommend its use at this time.[70] Caspofungin and the other echinocandins do not achieve adequate CSF concentrations for treatment of *Candida* meningitis,[30,124] but they do achieve appropriate brain parenchyma concentrations and have been successfully used for therapy.[62]

Cryptococcosis

Cryptococcal meningitis was rare in the United States in the pre-HIV era. With the growth of the AIDS epidemic, however, this infection has become the most common cause of fungal meningitis in immunocompromised patients and infects 2 to 9 percent of adults with AIDS.[24,33,81,175] In the United States and worldwide it remains an uncommon finding in pediatric patients.[91,107,129,148] Cryptococcosis is a systemic fungal infection, and meningitis is its most serious manifestation. Patients with initial pulmonary involvement may have few symptoms but can present with fever, cough, weight loss, and dyspnea on exertion.[99] In adult studies, progressively severe headaches without the presence of fever were common manifestations.[152] Patients with cryptococcal meningitis frequently have few symptoms but can present with nausea, dizziness, and irritability. Nuchal rigidity is usually absent. Careful examination for cranial nerve palsies, which are found in approximately one fifth of adult patients, should be performed. Diplopia, in particular, is one of the most common manifestations of cryptococcal meningitis. Papilledema is seen in nearly one third of patients with cryptococcal meningitis.[52] Patients with coexistent AIDS frequently have very few symptoms.[33]

Pediatric patients with cryptococcal meningitis usually have signs and symptoms not referable to the CNS.[142] Leggiadro and associates[89] reported 13 children with AIDS, compiled from 11 institutions, who were diagnosed with extrapulmonary cryptococcosis. Meningitis was diagnosed in 62 percent of these patients and was the most common clinical manifestation of extrapulmonary disease. Patients who initially responded to antifungal therapy did not die of the fungal infection but died of other illnesses related to their immunodeficiency. Death can occur, however, even in an immunocompetent child receiving effective therapy.[131]

Leggiadro and associates[88] also reported on eight children with acute lymphoblastic leukemia who developed extrapulmonary cryptococcosis. Of these immunocompromised children, 63 percent had meningitis. Fever was the most common symptom, occurring in 60 percent of the children with meningitis. Headache was present in only 40 percent. A significant number of the children (40%) were completely asymptomatic and had lumbar punctures performed as routine management of acute lymphoblastic leukemia, with the subsequent unexpected growth of *C. neoformans* on culture. One child had cutaneous lesions, and another had ptosis and an unsteady gait. Treatment in this series of patients included amphotericin B (intravenous, intrathecal, or both), alone or combined with oral flucytosine. In these patients with acute lymphoblastic leukemia, relapse was a major complication, occurring in 60 percent of patients thought to have been treated successfully. The relapses occurred within 2 to 6 months of completing therapy. Treatment of the relapses generally included combination therapy of amphotericin B and flucytosine, with the occasional use of intrathecal amphotericin B.

Other illnesses that may lead to cryptococcal meningitis include systemic lupus erythematosus being treated with corticosteroids alone or in combination with azathioprine,[2,88,92,126] chronic mucocutaneous candidiasis,[65,160] and hyper-IgE syndrome.[146] Zoonotic transmission from a pet cockatoo was described in an immunocompromised adult.[108]

Direct examination of the CSF using the India ink test can provide an immediate presumptive diagnosis of cryptococcal meningitis. The sensitivity of this test varies, but in studies of adult patients with AIDS, positive results with the stain approached 75 percent.[24] Other useful stains include silver, periodic acid–Schiff, and mucicarmine. Gram stain of CSF is insensitive and unreliable.

Diagnosis of cryptococcal meningitis is aided by the use of serologic tests. The most common test is the cryptococcal capsular polysaccharide antigen test, which can be performed on serum, CSF, or other sterile body fluids. The sensitivity of this test is nearly 100 percent for the serum of patients who are HIV-positive.[25,81,175] The CSF antigen test in some studies seems to be less sensitive (91%).[24] False-positive results caused by cross-reactions of antigens in disseminated infections with *Trichosporon beigelii* have been reported.[101] Culture is still the gold standard for establishing the diagnosis and monitoring the success of therapy.[121]

Treatment of cryptococcal meningitis is prolonged and, in immunocompromised patients, frequently requires lifelong maintenance therapy. Practice guidelines have been published for children with cryptococcal meningitis.[121] For HIV-negative, non–transplant recipient children, amphotericin B deoxycholate 1 mg/kg/day

plus flucytosine 100 mg/kg/day in four divided doses should be given for at least 2 weeks, as induction therapy, if no neurologic complications are present and CSF culture performed at 2 weeks of therapy is negative. Liposomal amphotericin B 5 mg/kg/day or amphotericin B lipid complex 5 mg/kg/day may be substituted for amphotericin B deoxycholate in those intolerant to the latter. In patients with neurologic complications, consideration for extension of the induction phase to 4 to 6 weeks using a lipid formulation of amphotericin B for the final 4 weeks of therapy should be made. Consolidation using oral fluconazole 10 to 12 mg/kg/day for 8 weeks follows. On completion of the consolidation phase, maintenance therapy with fluconazole 6 mg/kg/day should be started and continued for 6 to 12 months.

For HIV-infected children, the practice guideline study group recommends induction therapy consisting of amphotericin B 1 mg/kg/day plus flucytosine 100 mg/kg/day in four divided doses for 2 weeks, followed by consolidation with fluconazole 10 to 12 mg/kg/day for 8 weeks. In patients who cannot tolerate amphotericin B, the use of lipid formulations of amphotericin B should be considered, as described earlier.[87,121] A trial from Thailand evaluated sterilization of the CSF in 64 patients and revealed that the combination of amphotericin B plus flucytosine was the most rapidly fungicidal regimen.[17] Fluconazole 6 mg/kg/day is used for maintenance therapy for 1 year or longer. For adults receiving highly active antiretroviral therapy (HAART) with a CD4 cell count ≥100 cells/μL, and low or undetectable viral RNA level for ≥3 months, maintenance therapy may be discontinued after a minimum of 1 year, but should be restarted if the CD4 cell count falls below 100 cells/μL. In children receiving HAART, discontinuation of maintenance therapy is poorly studied and requires individualization. HIV and AIDS guidelines change frequently, and the physician should consult the most recent guidelines for changes, particularly with regard to need for prolonged maintenance therapy.

In patients with renal compromise associated with amphotericin B, flucytosine levels must be monitored carefully. The recommendation is that the dose of flucytosine be reduced based on glomerular filtration rate and continuing doses be adjusted to maintain serum flucytosine levels of 25 to 60 μg/mL.[6,42] Serum cryptococcal antigens are not useful in monitoring response to therapy, and the use of CSF cryptococcal antigens to monitor response to therapy also is controversial. Therapy is best judged to be successful by the demonstration of sterility of CSF fungal cultures.

Histoplasmosis

Infection with *Histoplasma capsulatum*, usually a benign and self-limited disease, is endemic in many parts of the United States. Disseminated disease, including meningitis, is a rare occurrence in children.[76,118] Case reports of adults generally describe immunocompromised individuals.[48,157] Clinical presentations reported in the literature show a wide variability in the manifestation of meningitis. In these cases, 39 percent of patients presented with meningitis associated with acute dissemination, 25 percent presented with single histoplasmoma that manifested as symptomatic mass lesions alone or with dissemination, 25 percent presented with chronic meningitis without evidence of dissemination, and the remaining patients presented with meningitis as a manifestation of recurrent disease. Rarely, embolization to the brain caused by *Histoplasma* endocarditis has been associated with meningitis.[167]

Meningitis occurring in patients with AIDS has become common in endemic areas. In one report, disseminated histoplasmosis caused 8 percent of the AIDS-defining illnesses in children.[136] The duration of symptoms varies. In patients who do not have AIDS, the symptoms generally last longer than 6 months and can last 7 years.[35,48,116,161] In patients with AIDS, symptoms usually manifest more acutely and in a much shorter time frame.[167] In one series, neurologic findings occurred in all but 6 percent of the patients.[167] The most common signs and symptoms include depressed consciousness (29%), headaches (24%), confusion (22%), cranial nerve deficits (19%), other focal deficits (16%), seizures (14%), personality changes (12%), and ataxia (11%). Findings more commonly observed with acute bacterial meningitis, such as meningismus, a Babinski sign, or papilledema, were seen in fewer than 8 percent of the cases. In adult patients who do not have AIDS, the death rate is approximately 12 percent, with a relapse rate of 44 percent. In adult patients with AIDS, the death rate is 100 percent in some series.[4,167]

Diagnosis can be aided by serologic testing. High levels of anti–*H. capsulatum* antibodies were detected in the serum of 70 percent of patients tested. CSF serology was helpful in 75 percent of patients who were tested. Culture of the CSF was positive for fewer than half of the cases in one review.[76] In a second series in patients with AIDS, blood cultures were positive for 49 percent, bone marrow cultures were positive for 53 percent, respiratory secretions cultures were positive for 58 percent, and brain or meninges cultures were positive for 75 percent of those tested. Serologic testing can be negative because 10 to 25 percent of patients with disseminated disease lack a positive antibody response. The serology also can be false-positive in patients with other fungal diseases or tuberculosis. The antibody response to acute *Histoplasma* infection may remain elevated for years, without evidence of dissemination or meningeal disease. The use of *Histoplasma* antigen has become widely held as a useful test in immunocompromised patients with disseminated *Histoplasma*. Data from Wheat and associates[167] showed that antigen was found in the urine of six of seven patients with AIDS and meningitis.

Treatment with liposomal amphotericin B 5 mg/kg/day given over 4 to 6 weeks, followed by itraconazole 200 mg or 5 mg/kg/dose 2 or 3 times daily for a minimum of 1 year and until CSF abnormalities have resolved, including *Histoplasma* antigen levels, is currently recommended.[166,169] The liposomal form provides higher CNS levels than the deoxycholate form. However, it should be noted that none of the amphotericin B formulations achieve detectable concentrations in the CSF.[169] The use of intrathecal amphotericin B is not recommended for *H. capsulatum* meningitis. Determination of itraconazole

serum trough blood levels should be performed to ensure appropriate drug levels.[170] Johnson and colleagues[71] reported on a trial comparing amphotericin B with liposomal amphotericin B (AmBisome, LAmB) as induction therapy and showed the agents had similar efficacy for treating disseminated histoplasmosis.

Patients with AIDS for whom induction therapy was successful must remain on an anti-*Histoplasma* agent indefinitely. A few cases of children with disseminated histoplasmosis and AIDS have been reported, but none with meningitis, and in these children, antifungal therapy must be continued indefinitely.[20,135] The case report by Schutze and associates[135] showed that ketoconazole was ineffective for preventing recurrence of nonmeningeal disseminated disease, and because ketoconazole has poor CNS penetration, it is likely to be ineffective for prophylaxis of meningitis. In patients with AIDS, some success has been achieved with the use of itraconazole for suppressive therapy in disseminated disease. However, few data exist on the use of itraconazole for suppressive therapy for meningitis or other CNS lesions caused by *Histoplasma*. For maintenance therapy, fluconazole (high-dose), itraconazole, or intravenous amphotericin B in a weekly dose of 1 mg/kg are available. In one case report, fluconazole was effective in an adult with *Histoplasma* meningitis refractory to amphotericin B therapy.[151]

Coccidioidomycosis

C. immitis (*Coccidioides posadasii* in Texas and Central and South America) meningitis is a more common cause of chronic meningitis than *Histoplasma*.[72] In endemic regions of the United States (southwestern United States, Central Valley of California), 200 to 300 cases of coccidioidal meningitis occur annually.[171] Approximately 1 percent of children with symptomatic pulmonary disease develop disseminated disease.[73] Of patients with disseminated coccidioidomycosis, 15 to 20 percent develop meningitis.[73,78] History of exposure is a crucial factor in diagnosing this disease and relies on careful questioning of the patient about travel to or residence in an endemic area.[147,149] Exposure of wounds to colonized soil has been implicated in at least one pediatric case.[106] An association between facial cutaneous coccidioidomycosis and meningitis has been described.[7]

CSF shows a mononuclear pleocytosis with an elevated protein and decreased glucose concentration. Elevated CSF pressures may herald the development of hydrocephalus.[171] Diagnosing coccidioidal meningitis is made easier by the availability of reliable serologic tests. Smith and associates[144] showed that complement-fixing antibodies appeared in the CSF only in patients with meningitis and provided a sensitivity of 76 percent. Sensitivity of 96 percent was seen when the complement-fixation test was incubated at 4° C.[113] McGinnis,[100] in his review of the literature based on pooling five studies, showed that *Coccidioides* could be cultured from the CSF in 76 percent of patients with meningitis and was seen on direct examination of the CSF in only 8 percent of the cases. He concluded that these values were too high and were likely skewed because of reporting bias. Other experts in the field also consider that the rate of positive CSF cultures is much lower (approximately 33%) and that finding the organism in the CSF by direct examination rarely occurs.[145]

Coccidioidomycosis in infancy was described more than 40 years ago and continues to be a problem today.[153] Infants usually have severe disease with high mortality rates and morbidity. In the 1980s, two studies described children with *Coccidioides* spp. meningitis who were treated with oral, intravenous, or intrathecal imidazoles.[60,139] The authors reported promising results with the use of ketoconazole and imidazole therapy compared with standard intravenous or intrathecal amphotericin B.

If untreated, *Coccidioides* meningitis is uniformly fatal. Therapy with intravenous and intrathecal amphotericin B reduced the mortality rate to 30 percent.[113] The use of fluconazole has been found in adult studies to have a success rate of 79 percent.[46] It seems to be safe in clinical use, despite a case report of a pregnant woman with *Coccidioides* meningitis treated with fluconazole who delivered an infant with congenital malformations. The infant was thought to have an autosomal recessive disorder (Antley-Bixler syndrome), however, and not teratogenic malformations caused by fluconazole.[86] Fluconazole may be the superior agent for sustaining remission of meningitis caused by *Coccidioides* because of its oral bioavailability, the toxicity associated with amphotericin B, and the elimination of the need for intrathecal administration.[120]

Galgiani and coworkers[45] have written practice guidelines for the treatment of coccidioidomycosis in adults. Therapy with oral fluconazole is preferred, with most authorities recommending 400 mg/day orally, although some physicians begin with higher doses of 800 to 1000 mg/day. Fluconazole 400 to 600 mg/day for 9 to 12 months has been shown effective in adults.[46,155] A corresponding dose of 6 mg/kg/day in pediatric patients also has been used, but no controlled studies using this agent in pediatric patients have been published. If treatment is begun with azole therapy, it should be continued for life.[31]

Itraconazole has proven efficacy in nonmeningeal coccidioidomycosis, with 63 percent of adult patients treated showing a complete response.[156] Itraconazole 400 to 600 mg/day has been reported effective in adults. Because itraconazole has variable oral bioavailability, many authorities recommend monitoring for adequate serum drug levels.[159] The use of itraconazole for meningeal involvement led to great hope for the use of an oral agent in this disease.[154] Adult patients with *Coccidioides* meningitis had high relapse rates (40% to 50%), which rendered them dependent on lifelong therapy with itraconazole.[54] The alternative of continued intrathecal amphotericin B renders this treatment much more appealing.

Well-developed, controlled clinical trials with large numbers of children do not exist for the azoles; some authorities consider intravenous and intrathecal amphotericin B to be the standard therapy for coccidioidal meningitis. It also is recommended for patients who do not respond to fluconazole or itraconazole treatment. Some experts initially use a combination of oral azole with intrathecal amphotericin B with the thought that

responses are more prompt with this approach. Amphotericin B can be administered intrathecally into the lumbar area or cisterna magna or by using an Ommaya reservoir.[29,47,83,174] In younger children, intraventricular or intracisternal therapy using the Ommaya reservoir allows ease of administration but has the disadvantage of increasing susceptibility to secondary bacterial infection.

The initial dose of amphotericin B administered into the CSF is 0.025 mg. The dose is increased by doubling until a maintenance dose of 0.1 to 0.5 mg is attained. After this dose has been achieved, therapy can be given every other day, alternating with intravenous administration of amphotericin B. Therapy is continued until the child's condition has stabilized, at which point intrathecal therapy gradually can be stretched out to every 3 weeks. This program is continued until the CSF indices are normal and culture results have been negative for at least 1 year.

Use of voriconazole has been successful in two case reports, and other similar anecdotal references have been reported at referral centers; some centers use voriconazole 4 mg/kg every 12 hours orally for salvage therapy.[27,45,125]

Blastomycosis

Blastomyces dermatitidis is an uncommon cause of chronic meningitis and is difficult to diagnose premortem unless the patient has other signs of systemic blastomycosis. When systemic blastomycosis occurs, it can involve the CNS in 5 to 10 percent of cases.[15] Importantly, a review of CNS cases of blastomycosis revealed that approximately 23 percent were not associated with disease outside the CNS.[9] Common sites for this organism include bone, genitourinary tract, and skin.[10,16] Previously, blastomycosis most often affected patients who were immunocompetent. A total of 55 percent of cases of CNS blastomycosis involve individuals with immunosuppressive conditions.[9] Patients with AIDS are at high risk for developing chronic infection.[59] Because of the difficulty in diagnosing meningitis caused by *B. dermatitidis* and its similarities to tuberculous meningitis, patients usually are treated for presumptive tuberculous meningitis.[51,105] Although meningitis is the most common form of CNS blastomycosis, solitary mass lesions also can occur.[130] A review of 22 cases treated from 1990 to 2008 demonstrated a mortality rate of 18 percent.[9]

Examination of CSF obtained by lumbar puncture usually is negative.[9] However, the yield from ventricular fluid (four of four patients tested) seems to have a higher yield.[82] Diagnosis relies on the characteristic histopathologic appearance in tissues and occasionally on culture of CSF obtained from the ventricles. Isolation of *Blastomyces* from the CSF by culture is possible in approximately half of cases.[9] Testing for the presence of *B. dermatitidis* antigen may yield better results. In one report, all three CSF samples tested using a commercially available assay were found to be positive. Blastomycosis meningitis is associated with a pleocytosis that may be lymphocytic or neutrophilic in nature.[9] The CSF protein is elevated in the majority of cases.[9] Meningitis caused by *B. dermatitidis* frequently has a neutrophilic predominance.[9,59] If the difficulty in performing these procedures is prohibitive, looking for other sources of blastomycosis, including sputum and urine, is indicated. A study in patients with AIDS showed that examination of sputum was useful for establishing the diagnosis of disseminated blastomycosis.[115]

Treatment of CNS blastomycosis relies on the administration of lipid formulation of amphotericin B in a dose of 5 mg/kg/day for 4 to 6 weeks, followed by oral azole therapy (i.e., fluconazole 800 mg/day, itraconazole 200 mg 2 or 3 times per day, voriconazole 200 to 400 mg/day) for a minimum of 12 months or until CSF abnormalities have resolved.[22] For children, no specific recommendations exist for the treatment of CNS disease, although for children with severe blastomycosis amphotericin B deoxycholate 0.7 to 1 mg/kg/day or lipid formulation of amphotericin 3 to 5 mg/kg/day is recommended for initial therapy. Itraconazole 10 mg/kg/day (up to 400 mg/day) divided twice daily is recommended as follow-up therapy for 12 months.[22] A recently published review favors the use of voriconazole as the azole of choice after initial therapy with lipid formulation of amphotericin.[9] Azoles should not be considered for primary treatment of CNS blastomycosis. Schutze and colleagues[136] reported that children respond less satisfactorily to oral azole therapy than do adults. Although only a few published reports existed for the use of lipid formulations of amphotericin B to treat CNS blastomycosis, these drugs are preferred because of the need of prolonged duration of therapy in these patients. Experimental animal data exist demonstrating superior penetration of liposomal amphotericin B compared with lipid complex or the deoxycholate formulations of amphotericin.[55]

Aspergillosis

CNS infections with *Aspergillus fumigatus* and other *Aspergillus* spp. in immunocompromised patients usually are fatal. Conditions that place the patient at risk include organ transplantation, malignancies, and neutropenia. In most reported cases, patients were receiving high-dose corticosteroid therapy in addition to broad-spectrum antibiotics.[11,84] Many patients had fever, and pulmonary findings preceded neurologic manifestations. *Aspergillus* infection of the CNS usually is acquired by hematogenous spread from the lungs. Other modes of acquisition include extension from a contiguous focus (sinuses) and intravenous drug abuse.[104]

Brain abscesses are the most typical manifestation of *Aspergillus* spp. infection in the CNS, but meningoencephalitis, isolated spinal cord lesions, aqueductal stenosis, and mycotic aneurysms also have been described.[21,39,158,162,173] Magnetic resonance imaging has been suggested to be superior to computed tomography for the delineation of CNS lesions in patients with bone marrow transplantation.[102] The lesions are consistent with acute infarcts.

Some early reports of CNS aspergillosis were in infants who appeared to be normal.[1,96] The diagnosis of meningitis relies on CSF cultures, but the results of bronchoscopy or biopsy frequently are more helpful and provide a more expedient diagnosis. Use of *Aspergillus*

antigen in the CSF has been helpful, and it may be used for serial observations during the course of therapy.[163] Because the disease is uniformly fatal, the importance of treating pulmonary aspergillosis before the development of meningeal involvement cannot be overemphasized.

No specific recommendations for therapy of CNS *Aspergillus* infections are published for children. Published practice guidelines for the therapy of adults supports the use of voriconazole as the primary recommendation for antifungal therapy of CNS aspergillosis.[164] For those intolerant to or who fail to respond to voriconazole therapy with itraconazole, posaconazole or lipid formulations of amphotericin B should be attempted. Itraconazole has been used successfully in one case report, as has voriconazole.[103,163] Combination therapy using voriconazole and an echinocandin antifungal shows promise, but no definitive studies exist to date.

Sporotrichosis

Although primarily a lymphocutaneous disease, *S. schenckii* has been reported to cause meningitis.* Many of the cases described more recently have occurred in adults with AIDS as an underlying risk factor.[34,56] Meningeal seeding may occur through hematogenous spread from the lungs, as is seen in most other fungal infections.[36] Meningeal involvement with sporotrichosis produces CSF indices and abnormalities similar to those seen with the other fungal meningitides.[35,56] CSF fungal culture is insensitive for the diagnosis of meningitis caused by sporotrichosis. The use of *S. schenckii* antibody in the CSF has been effective in diagnosing meningitis in patients without other overt signs of this infection.[137]

Treating this infection is very difficult. Practice guidelines for adults recommend amphotericin B given as a lipid formulation at a dosage of 5 mg/kg/day for 4 to 6 weeks as initial therapy.[77] The expert panel did not prefer amphotericin B deoxycholate over a lipid formulation. Step-down therapy using itraconazole 200 mg twice daily is recommended once the patient responds to initial therapy using amphotericin B. Itraconazole should be continued for at least 12 months. Monitoring of serum levels is recommended to ensure adequate drug exposure.[53] For patients with immunosuppressive diseases or conditions, itraconazole suppressive therapy, 200 mg daily, is recommended.

Mucormycosis

Meningitis caused by *Mucor* spp. or other Zygomycetes usually occurs as a result of direct extension from paranasal sinus disease. Infection with these organisms most commonly is seen in the immunocompromised host and particularly in patients with diabetes mellitus or patients receiving high doses of corticosteroids. Patients (particularly dialysis patients) undergoing chelation therapy with deferoxamine are at risk for developing infection.[13,14,75,172] The association with deferoxamine therapy is seen with *Cunninghamella*.[127] *Mucor* spp. have been reported as a cause of CNS disease in children but very rarely.[57,67] Treatment employs amphotericin B in doses of 1 to 1.5 mg/kg/day or lipid formulations. Improved survival has been seen among cancer patients with mucormycosis of the head and neck with treatment using liposomal amphotericin B.[28] Surgical excision of rhinocerebral infection is recommended along with antifungal therapy. In two compassionate use case series of posaconazole in patients with refractory mucormycosis or intolerant to standard therapy, an oral azole produced encouraging results.[28] Importantly, voriconazole has no antifungal activity against mucormycosis.

Other Fungal Infections

Acremonium spp. are common soil fungi that may cause chronic meningitis in humans.[111] *Xylohypha bantiana*, an uncommon dematiaceous fungus, caused a fungal brain abscess in an adolescent girl; this report increases the number of cases reported in the literature to nearly 40.[110] Cerebral chromoblastomycosis also has been reported.[140] Other fungal organisms causing CNS infection include *Paracoccidioides brasiliensis* (i.e., South American blastomycosis),[119] *Prototheca wickerhamii*,[74] *Blastoschizomyces capitatus*,[49] *Rhodotorula* spp.,[97,123] *Pseudallescheria boydii*,[12] *A. mansoni*,[64] *C. lusitaniae*,[64] and *B. spicifera*.[85]

DIAGNOSIS

Specific information about the diagnosis of individual organisms is provided in the previous sections. Table 33-1 provides specific data for some fungal meningitides. Overall, the problem with diagnosing many of these infections is that most patients have nonspecific signs and symptoms without reference to the CNS. Standard culture media may not be useful for these organisms, and it can take weeks before an organism is identified on culture. The use of antigen and antibody testing has proved quite useful for the diagnosis of *Cryptococcus*, *Coccidioides*, and *Histoplasma* infections. The hope is that polymerase chain reaction technology may be helpful in the future, as it has been for bacterial and mycobacterial diagnoses. Neonates may have only a mild CSF pleocytosis. In one series of 16 neonates with definite *Candida* meningitis, the median CSF white blood cell count was 53 cells/mm^3 (range, 0 to 1120 cells/mm^3).[40]

CSF examination may be helpful in some instances. As much CSF as can be removed safely should be obtained, especially at the time of ventriculography or pneumoencephalography.[35] A minimum of 5 mL of spinal fluid has been suggested, based on experimental work.[94] Repeated cultures of large volumes of CSF may be helpful.[35] The fluid obtained should be centrifuged and the sediment saved for culture and India ink preparation. The supernatant is sent for serologic tests. The India ink test should be interpreted with caution and must be followed with cultures because artifacts frequently can cause misinterpretation.[35] The cumulative efficacy of repeated lumbar punctures for cryptococcal meningitis improved the sensitivity of the India ink smear from 26 percent in one lumbar puncture to 52.6 percent with the second.[100] If large volumes are available, membrane filtration may be

*References 36, 43, 56, 80, 117, 141.

TABLE 33-1 **Fungal Cerebrospinal Fluid Characteristics**

Organism	WBCs	Protein	Glucose	Smears	Serology	Cultures
Blastomyces	Variable up to 15,000 cells/mm^3 with PMNs or lymphocytes	Elevated up to 300 mg/dL	Normal or low	Rare on smear	No good serology	CSF cultures rarely positive; increased yield with ventricular taps
Candida	Mean 600 cells/mm^3 up to 1900 cells/mm^3 with lymphocytes or PMNs	Elevated	Low or normal	40% positive on smears	Serology not helpful	CSF cultures useful
Coccidioides	100-750 WBCs, mostly lymphocytes	150-2000 mg/dL	21%-62% serum	Rare on smear	CSF CF antibody positive in 75%-95%	CSF cultures positive in 33%-60%
Cryptococcus	40-400 WBCs, mostly lymphocytes	High	Low	India ink positive in 25%-50%	CSF and serum cryptococcal antigen positive in 85%-90%	CSF cultures positive in 75%
Histoplasma	0-300 WBCs, lymphocytes, or PMNs; most 11-101/mm^3	Usually elevated, but can be normal	Usually low (<40 mg/dL) to normal	Rare on smear	Polysaccharide antigen in urine, blood, CSF positive in 61%	CSF cultures positive in 27%-65%

used to concentrate the fungal elements. The membrane containing the fungi is placed aseptically on isolation media and incubated at 30° C for 4 weeks. The CSF that passes through the membrane can be used for serology or chemistry determinations.[100] The remaining CSF can be inoculated onto Sabouraud glucose agar, blood agar, and brain-heart infusion agar or into broth media or into both types of media. CSF cultures generally are unhelpful for *Histoplasma*, *Blastomyces*, and other dimorphic fungi.

Serologic techniques are extremely useful for *Cryptococcus* and *Coccidioides*. Approximately 100 percent sensitivity is seen with serum cryptococcal antigen tests in HIV-positive patients.[25,81,175] The CSF antigen test in HIV-positive patients seems to be less sensitive (91%) in some studies.[24] In patients not infected with HIV, the sensitivity of the serologic test in the CSF approaches 90 percent.[61] For coccidioidal meningitis, the sensitivity rate is greater than 76 percent.[113,144]

Candida can be cultured but may require a prolonged incubation period, necessitating institution of empirical therapy while awaiting results of cultures. For other organisms, such as *Histoplasma*, *Blastomyces*, and *Coccidioides*, culturing other body fluids, such as blood, urine, sputum, or draining wounds, can be helpful.

CONCLUSION

With the large increase in the number of immunocompromised children caused by the epidemic of HIV, the advent of new antineoplastic agents, the growth of organ transplantation, and the increased use of corticosteroids, the relative rarity of fungal meningitides has been replaced by a burgeoning upswing in the incidence and prevalence of these infections. New modalities for diagnosis are needed because many of these fungal infections still require weeks for identification. Future trials in progress will help determine the role of azoles, amphotericin B, lipid formulations of amphotericin B, or combinations of these drugs as the optimal treatment of many fungal meningitides.

CHAPTER 34

Eosinophilic Meningitis

Barbara W. Stechenberg

Eosinophilic meningitis may include any meningitis, infectious or noninfectious, in which cerebrospinal fluid (CSF) pleocytosis with a significant percentage of eosinophils is found. The diagnosis of eosinophilic meningitis can be made by the presence of 10 or more eosinophils in the CSF or if at least 10 percent of the CSF leukocytes are eosinophils.[20] Such a finding strongly suggests invasion of the central nervous system (CNS) by a helminthic parasite. In the last 40 years, the term *eosinophilic meningitis* has been applied more specifically to a typical form of meningitis caused by *Angiostrongylus cantonensis*, a rat lungworm found primarily in the Pacific Islands and Southeast Asia. *Gnathostoma spinigerum* and *Baylisascaris procyonis* also may be considered in particular circumstances.

The first documented case of eosinophilic meningitis was reported from Taiwan in 1945.[1] The patient was a 15-year-old boy who developed severe headache and vomiting. Examination of the CSF revealed 528 leukocytes, of which 50 percent were eosinophils. Ten actively moving nematodes also were recovered from the specimen. Since the early 1960s, many new cases have been reported, with particularly large numbers coming from Thailand,[29,30] Tahiti,[34] Taiwan,[49] and Hawaii.[14,17]

ETIOLOGIC AGENTS

The organism that presumably is involved in most cases is the rodent lungworm. *A. cantonensis*, which as an adult is 17 to 25 mm long and 0.25 to 0.36 mm at its maximum width, has a smooth cuticle and three minute lips at the cephalic end. The male has a copulatory bursa supported by bursal rays.

In its life cycle, rodents such as *Rattus rattus* are the principal hosts. These rodents ingest mollusks containing third-stage larvae, which travel from the liver and lung into the general circulation. The larvae selectively leave the circulation to enter the CNS within the first 48 hours. There they develop into young adults in approximately 2 weeks.[46] From the brain, they travel to the pulmonary arteries, where their eggs are laid. The eggs hatch in the pulmonary capillaries; the first-stage forms then travel from the alveolar spaces up the rat trachea to the gastrointestinal tract, from which they are eliminated in the feces. The larvae can survive for approximately 2 weeks under humid conditions. The third-stage larvae develop in the intermediate hosts in approximately 2 weeks.

Another form of eosinophilic meningitis has been attributed to the nematode *G. spinigerum*. The adult *G. spinigerum* is stout and reddish and has a globose cephalic bulb that is separated from the body by a slight constriction. The head and anterior part of the body have spines. Males may be 11 to 25 mm long, and females may be 25 to 54 mm long. The adults lie coiled in lesions along the alimentary canal, from which they release eggs into the feces, where they become embryonated. The eggs hatch on reaching water, releasing a larva that is ingested by a copepod *(Cyclops)* and continues to develop. When the infected copepod is eaten by a fish, frog, snake, or bird, a third-stage larva develops and becomes encapsulated in the intermediate host. When it is ingested by the definitive host (i.e., cats, dogs, hogs, mink, and humans), the parasite localizes in the stomach wall.[37]

The adult worms of *B. procyonis*, the raccoon ascarid, reside in the intestines. They are large, tan-colored roundworms; the female is 20 to 22 cm long, and the male is 9 to 11 cm long. Infection in raccoons usually is

subclinical, with the adult female worm producing 115,000 to 179,000 eggs/worm/day, most of which are shed in feces.[12] Young raccoons have a higher prevalence of infection and higher parasitic burden; in their first few months of life, they ingest eggs that are in their environment or sticking to their mothers' fur.

EPIDEMIOLOGY

The geographic distribution of eosinophilic meningitis from angiostrongyliasis depends on the distribution of *A. cantonensis*. Many cases have been reported from Taiwan and Thailand. Other areas include Vietnam, the Society Islands (especially Tahiti), Hawaii, the Marshall Islands, and Ponape. Rodents infected with the worm have been documented in other areas of the Pacific Islands and Asia. Disease has been reported from Cuba, Egypt, and many other countries. As infected rodents are carried to other countries on cargo ships, spread of these organisms will continue to increase. Several cases have been diagnosed in the continental United States in travelers from endemic regions.[13,16] An outbreak was described in 12 of 23 young adults who had traveled together to Jamaica.[19,41]

The seasonal incidence of the disease varies in different areas. The months of highest prevalence usually correspond with the more humid periods in each country.

Patients with eosinophilic meningitis have eaten terrestrial snails, slugs, fish, or fresh-water shrimp, all of which can serve as intermediate hosts for the parasites.[44,45] In Thailand, the most common source is the *Pila* snails, which are eaten raw or pickled.[28] They may be served as an appetizer with alcoholic beverages, which may partly explain the increased incidence of the disease in men.[29] The giant African snail *Achatina fulica* is found commonly in Taiwan and may carry thousands of roundworm larvae, explaining the higher incidence of recovery of organisms from the patients in Taiwan.[45] The larvae also may remain infective in water for approximately 60 hours. Cases have been associated with the ingestion of leafy vegetables, presumed to be contaminated by slugs or snails.[17]

The distribution of disease among age groups varies. In Thailand, most of the cases occur in the third to fourth decades of life, but in Taiwan and Hawaii, most cases occur in children younger than 15 years old.[29,49] Although eosinophilic meningitis rarely occurs in very young children, one report documented disease in five children younger than 2 years.[40]

The first confirmed cases of *B. procyonis* neural larva migrans were described in the 1980s in 10-month-old and 18-month-old boys from Pennsylvania and Illinois, respectively.[11,15] Both boys had rapidly progressive, fatal eosinophilic meningoencephalitis. Subsequent reports of fatal and nonfatal disease have been reported from areas with large raccoon populations. They have occurred in rural, urban, and suburban areas. Two risk factors for acquisition of severe infection are contact with raccoons, particularly baby or young animals, or their feces or a contaminated environment, and pica or geophagia. Outdoor contamination of children's play areas by raccoons and proximity of raccoon communal latrines to human habitation may contribute to risk.[35]

PATHOGENESIS

For angiostrongyliasis, the pathogenesis of this disease in humans has not been studied rigorously but is presumed to parallel the pathogenesis in the rodent host. The larvae are ingested, make their way into the general circulation, and selectively enter the CNS. The number of nematodes found on autopsy specimens has varied. In a 5-year-old Taiwanese girl, 150 nematodes were found on the surface of the cerebrum and cerebellum and in the subarachnoid spaces, and more than 500 were recovered from the normal saline in which the spinal cord and meninges were placed. *A. cantonensis* also were found in the pulmonary arteries.[49]

Pathologic specimens have shown a leptomeningitis in which plasma cells and eosinophils predominate. Tortuous tracks of variable size in the brain and spinal cord parenchyma surrounded by variable reaction and degenerating neurons may be present. Granulomata may form around dead *A. cantonensis*.[26]

Hemorrhagic, necrotic tracts caused by the organisms have been associated more commonly with *G. spinigerum* infection.[4] *Angiostrongylus* is capable of causing a vascular reaction, however, including thrombosis and rupture of vessels and arteritis, leading to formation of an aneurysm.[26] The tracts caused by *G. spinigerum* may be larger and more necrotic.

In baylisascariasis, information about the pathology is based on a few fatal cases with massive larval invasion of the CNS.[12] Swelling of the brain, leptomeningeal congestion, and evidence of herniation have been seen. Necrosis is most marked in the periventricular white matter. Large deposits of eosinophils are present along necrotic migration tracts.

CLINICAL MANIFESTATIONS

On the basis of information obtained from patients with a history of ingestion of the intermediate hosts, the incubation period is 7 to 30 days. Most patients with typical eosinophilic meningitis have an abrupt onset of disease; a more insidious onset may be noted in 20 percent of cases. Headache is the most common and distressing symptom. It usually is intermittent but is frequent and severe. Other common symptoms are nausea, vomiting (often projectile), intermittent somnolence, malaise, anorexia, constipation, and fever with temperatures usually reaching a maximum of 38° to 39°C (100.4° to 102.2°F) in the early phase of the disease, although many patients have no documented fever. Nuchal rigidity is seen more commonly in older patients, often in association with severe headache. Paresthesias occur in a large variety of locations and are expressed as pain, numbness, itching, or a sense of worms crawling on the skin. Some patients also note diplopia with or without strabismus. Convulsions are unusual occurrences.

The findings on physical examination are normal in half the patients. Physical findings may include mild hepatomegaly, mild changes in deep tendon reflexes (usually decreased), nuchal rigidity, absent abdominal wall reflexes, and, less commonly, ophthalmoplegia or

facial paralysis. Twelve percent of Thai patients had abnormal ophthalmoscopic examinations.[16]

Examination of the CSF reveals grossly turbid or opalescent fluid in most patients, with leukocyte counts usually 100/mm^3 to 5000/mm^3. All counts usually reach their maximum in the first 3 weeks of disease, decreasing sharply thereafter. Generally, the percentage of eosinophils in the CSF is high, often greater than 50 percent. Fluids with higher cell counts tend to have a higher percentage of eosinophils.[30,49] The proportion of eosinophils may decrease after the first 4 weeks. CSF protein concentration is moderately high (often 50 to 200 mg/dL), but the glucose concentration usually is normal.

Peripheral white blood cell count varies, but the differential cell count often shows striking eosinophilia. Examination of the feces may reveal concurrent infestation with other parasites, such as *Ascaris* or *Trichuris*.

The clinical manifestations of the eosinophilic radiculomyeloencephalitis associated with *G. spinigerum* overlap to some degree with the manifestations of typical eosinophilic meningitis. Headache is less prominent, however. Many patients report sharp, shooting pains of the trunk or limbs, flaccid paralyses, and impairment of superficial sensation.[31] Impairment of the sensorium may be sudden in association with cerebral hemorrhage. Grossly bloody spinal fluid is a common finding when myeloencephalitis is present, but it is extremely rare in typical eosinophilic meningitis.

Patients with baylisascariasis develop an acute fulminant eosinophilic meningoencephalitis; early features include low-grade fever, increasing lethargy, ataxia, somnolence, and irritability. Progression to posturing, spasticity, and ocular or cranial nerve involvement occurs. Seizures are common occurrences. Continued deterioration to coma and death may occur, or, with survival, to a persistent vegetative state or severe deficits.

DIAGNOSIS

The diagnosis of cerebral angiostrongyliasis usually is based on the clinical presentation with associated CSF eosinophilia and an epidemiologic history consistent with possible exposure to the *A. cantonensis* larvae. Rarely, larvae may be recovered from the CSF. Two thirds of patients also have peripheral eosinophilia. Enzyme-linked immunosorbent assay helps confirm the diagnosis.[10,42] Dot-blot ELISA kits for rapid diagnosis in the field have been developed that are simple and effective.[10] Newer immunoblotting analyses show excellent specificity for the diagnosis of angiostrongyliasis and gnathostomiasis in endemic areas.[38] The absence of focal findings on computed tomography and abnormal enhancement in the globus pallidus may be valuable in establishing a diagnosis.

Gnathostomiasis often is associated with xanthochromic or bloody CSF with an eosinophilic pleocytosis. Peripheral eosinophilia often is pronounced. Computed tomography and magnetic resonance imaging show areas of hemorrhage.[35] Immunoblotting serologies are available,[10] but definitive diagnosis is by recovery of the pathogen, which may be found in subcutaneous tissue.

Baylisascariasis should be suspected in a child with CSF and peripheral eosinophilia, with severe encephalopathy with diffuse white matter disease on neuroimaging,[36] and with or without eye disease in North America or Europe. A history of exposure to raccoons or their feces would strongly suggest the diagnosis. In the absence of brain biopsy, the diagnosis is made serologically.[15]

DIFFERENTIAL DIAGNOSIS

Other helminths may invade the CNS of humans and may be associated with an eosinophilic pleocytosis,[13,47] including *Taenia solium*, the pork tapeworm causing cerebrospinal cysticercosis; *Schistosoma* spp.; *Paragonimus westermani*; and *Echinococcus*. The diseases produced generally have a chronic and intermittent course. Signs of a space-occupying lesion and convulsions are found frequently. Visceral myiasis with invasion of the CNS by botfly larvae may cause CSF eosinophilia.[3] The larvae of *Trichinella spiralis* can invade the CNS, but pleocytosis seems to be an unusual occurrence.[3,13] Neurologic involvement in visceral larva migrans caused by *Toxocara canis* can occur; it may be associated with CSF pleocytosis and eosinophilia.[23,43] Rarely, eosinophilic pleocytosis can be seen in coenosis and filariasis.[13]

Coccidioidomycosis is the one fungal infection that may be associated with CSF eosinophilia when infection involves the meninges.[33,39] In one series, 30 percent of cases with coccidioidal meningitis had significant CSF eosinophilia.[33] Neurosyphilis and tuberculous meningitis rarely have been associated with eosinophils in the CSF, as have several malignant neoplasms, particularly lymphomas, involving the CNS.[18,24] Other known causes of significant eosinophilic pleocytosis include intrathecal injection of various foreign proteins, rabies vaccination, the insertion of rubber tubing into the CNS during neurosurgery, lymphocytic choriomeningitis,[18] and Rocky Mountain spotted fever.[9] Eosinophilic pleocytosis has been documented in infants with congenital toxoplasmosis and late-onset group B streptococcal meningitis.[22,48]

Eosinophilia in the CSF indicating hypersensitivity has been difficult to document, although one case report described the association of eosinophilic meningitis and ibuprofen therapy.[32] Eosinophilic meningitis developing after implantation of a ventriculostomy catheter impregnated with rifampin and minocycline has been reported.[2] A study documented more than 5 percent eosinophils in the ventricular fluid of patients with shunt-associated pathology, particularly malfunction.[21]

TREATMENT

In a study in Thailand in which the disappearance of headache was used as the criterion for improvement in patients with *A. cantonensis* meningitis, no significant differences were noted among groups when 284 patients were treated with analgesics alone, 96 patients were treated with analgesics and steroids (prednisone 30 to

60 mg/day for 5 days), and 56 patients were treated with analgesics and antibiotics (penicillin or tetracycline).[25] A study that compared adult patients given a 2-week course of prednisolone (60 mg/day) with patients treated with a placebo showed a significant decrease in the number of patients with headache and in the duration of headache in the prednisolone-treated group.[6] The combination of albendazole or mebendazole with prednisolone has shown promise.[7,8] However, a recent randomized, controlled trial comparing prednisolone and albendazole with prednisolone alone showed no added benefit from the albendazole.[5] Treatment of gnathostomiasis is supportive, although steroids have been used to decrease meningeal inflammation. Baylisascariasis has no known effective anthelminthic therapy, although treatment with albendazole and corticosteroids has been used.

COURSE AND PROGNOSIS

In most patients, eosinophilic meningitis is a self-limited disease characterized by repeated attacks of severe headache, vomiting, intermittent fever, and somnolence. Many patients experience a dramatic improvement soon after undergoing a lumbar puncture, so repeated lumbar punctures may be performed at weekly intervals to relieve the headache. In most patients, most symptoms disappear within 4 weeks of onset, often within a few days after the first lumbar puncture is performed, leaving no sequelae. The mortality rate in large series from Thailand and Taiwan has been less than 5 percent; the incidence of permanent sequelae also has been less than 5 percent for *Angiostrongylus* infection.[13,30] The mortality in gnathostomiasis is higher, ranging from 7.7 to 25 percent.[37] No evidence suggests that immunity develops after recovery from infection; many recurrences have been reported.[30,34,49] In baylisascariasis, the mortality rate is high, and survivors often have severe sequelae. A recent case in a 4 year old documenting full recovery is encouraging.[27]

PREVENTION

Disease can be prevented only by control of rodents and proper cooking of mollusks, shrimp, fish, and other intermediate hosts. Careful washing of fruits and vegetables that may be contaminated by rodent feces also is important. The larvae may remain infective in water for 60 hours, so protection of the water supply should be attempted. Prevention of baylisascariasis depends on eliminating exposure to raccoon feces.

meningitis. *Serous meningitis*, *lymphocytic meningitis*, and *nonparalytic poliomyelitis* are terms that were used in the past to denote aseptic meningitis.

HISTORY

Aseptic meningitis is a syndrome that first was described by Wallgren in 1925.[346] Wallgren's criteria for this diagnosis included (1) an acute onset with obvious signs and symptoms of meningeal involvement; (2) alteration of CSF typical of meningitis, which may show a small or large number of cells; (3) absence of bacteria in the CSF, as shown by appropriate culture; (4) a relatively short, benign course of illness; (5) absence of local parameningeal infection (e.g., otitis, sinusitis, or trauma) or a general disease that might have meningitis as a secondary manifestation; and (6) absence from the community of epidemic disease, of which meningitis is a feature. In 1951, Wallgren[345] redefined aseptic meningitis as a syndrome likely to be encountered in many different infectious diseases.

The clinical occurrence of aseptic meningitis first was recognized in epidemic poliomyelitis and in mumps at the beginning of the 20th century.[106,353] Rivers and Scott[274] reported the recovery of lymphocytic choriomeningitis virus from the CSF of several patients with aseptic meningitis in 1935, and in 1934, Johnson and Goodpasture[173] proved that mumps was caused by a virus. The discovery of coxsackieviruses in 1948 by Dalldorf and Sickles[86] and the introduction of tissue culture in 1949 by Enders and colleagues,[107] which resulted in the discovery of echoviruses, paved the way for the widespread investigation into the etiology of aseptic meningitis.

Rasmussen[268] reported on 374 cases evaluated at the Walter Reed Army Institute of Research laboratory between 1941 and 1946 and found the probable or definite etiology in 26 percent of "viral" disease of the central nervous system (CNS). Mumps and lymphocytic choriomeningitis viruses were the two etiologic agents identified in his study.

In 1953, Adair and associates[5] reviewed 480 additional cases of aseptic meningitis occurring in military personnel and their dependents from 1947 through 1952 and were able to confirm the etiology in 25 percent of those patients. Herpes simplex virus (HSV) and *Leptospira* spp. were added to the previously identified mumps and lymphocytic choriomeningitis viruses as causes of aseptic meningitis. Meyer and associates[226] extended these studies to include 713 more children and adults with acute CNS syndromes of "viral" etiology admitted to military and Veterans Administration hospitals between 1953 and 1958. Of these 713 patients, 430 had the clinical syndrome of aseptic meningitis. Approximately 80 percent of these patients were hospitalized in the United States. An etiologic diagnosis was determined in 71 percent of patients with aseptic meningitis. In addition to the agents identified earlier, poliovirus, coxsackieviruses of groups A and B, echoviruses, and arthropod-borne viruses were identified as causes of aseptic meningitis.

Lepow and colleagues[201,202] reported the probable viral etiology in 54 percent of the 407 patients they studied in Cleveland between 1955 and 1958. In 1958, Lennette and associates[200] determined a viral etiology in 65 percent of 511 children and adults with presumed viral CNS system disease in Los Angeles; 368 of these patients were diagnosed as having aseptic meningitis. Sköldenberg[302] analyzed 3117 patients admitted to the Hospital for Infectious Diseases in Stockholm between 1955 and 1964 with the diagnosis of aseptic meningitis, with or without encephalitis or myelitis, and a virologic or clinical diagnosis (or both) of an associated viral infection was established in 72.6 percent. Berlin and associates[27] performed a surveillance study of aseptic meningitis in pediatric ambulatory clinics and emergency departments of three Baltimore hospitals between July 1986 and December 1990. They identified a single viral agent in 169 (62%) of the 274 cases with laboratory study; 168 enteroviruses and 1 adenovirus were identified. Today, with the use of polymerase chain reaction (PCR) and culture and appropriate serologic study, the etiology of most cases of aseptic meningitis can be determined.

ETIOLOGY

Table 35-1 lists infectious agents and other causes of aseptic meningitis. At present, the diagnostic workup of aseptic meningitis usually is not undertaken vigorously, and the etiologic agent is identified in only approximately 10 percent of all cases. Epidemiologic study and intensive investigations at some centers indicate, however, that most cases result from viral infections. Enteroviruses account for approximately 85 percent of all cases of aseptic meningitis.[48,90-92,233] The following enteroviruses have been associated with aseptic meningitis: polioviruses 1 to 3; coxsackieviruses A 1 to 14, 16 to 18, 21, 22, and 24; coxsackieviruses B 1 to 6; echoviruses 1 to 9, 11 to 21, 24 to 27, and 29 to 33; enterovirus 71. Parechoviruses, a newly described family of viruses, closely related to enterovirus, have also been associated with aseptic meningitis. Thus far, 16 genotypes of parechoviruses have been characterized[69]; some have been associated with aseptic meningitis, but because these viruses are so newly described, it is unknown which will play important roles.[138,150]

In recent years, multiple outbreaks of aseptic meningitis caused by enteroviruses have been described, including outbreaks caused by echovirus 30 in several countries throughout Eastern and Western Europe, China, Japan, Korea, Australia, the Arabian Gulf, the United States, and Brazil.* Echovirus 13 was responsible for reported outbreaks of aseptic meningitis in the United States, England, Wales, Germany, Belgium, Spain, France, Lithuania, Israel, Japan, Korea, and Australia.† Enterovirus 71 caused a major epidemic in Taiwan from 1998 to 1999, with multiple cases of hand, foot, and mouth syndrome

TABLE 35-1 Etiologic Agents, Factors, and Diseases Associated with Aseptic Meningitis

Viruses

Adenoviruses (1, 2, 3, 5, 6, 7, 12, 14, 32)
Arboviruses (in the United States: West Nile, St. Louis, California, Colorado tick fever, Eastern equine, Western equine, Venezuelan equine, and Powassan)*
Coronaviruses
Cytomegalovirus
Encephalomyocarditis
Enteroviruses (echoviruses, coxsackieviruses A and B, polioviruses, enteroviruses)
Epstein-Barr
Hendra and Nipah
Herpes simplex type 1
Herpes simplex type 2
Human herpesvirus–6
Human herpesvirus–7
Human immunodeficiency virus (HIV-1)
Human T-cell lymphotrophic virus (HTLV-1)
Influenza A and B
Lymphocytic choriomeningitis
Measles
Mumps
Parechoviruses
Parainfluenza
Parvovirus B19
Rhinoviruses
Rotaviruses
Rubella
Varicella-zoster
Variola

Bacteria

Atypical Mycobacteria
Bartonella henselae
Borrelia spp. (relapsing fever)
Borrelia burgdorferi (Lyme disease)
Brucella spp.
Leptospira spp. (leptospirosis)
Mycobacterium tuberculosis
Nocardia spp. (nocardiosis)
Pyogenic: Partially treated
Treponema pallidum (syphilis)

Rickettsia

Anaplasma phagocytophila
Coxiella burnetii
Ehrlichia chaffeensis
Rickettsia rickettsii (Rocky Mountain spotted fever)
Rickettsia prowazekii (typhus)

Mycoplasma

Mycoplasma hominis
Mycoplasma pneumoniae

Chlamydia

Chlamydia pneumoniae
Chlamydia psittaci

Ureaplasma

Ureaplasma urealyticum

Fungi

Blastomyces dermatitidis
Candida spp.
Coccidioides immitis
Cryptococcus neoformans
Histoplasma capsulatum
Other: *Acremonium* spp., *Alternaria* spp., *Aspergillus* spp., *Blastoschizomyces capitus, Cephalosporium* spp., *Cladosporium trichoides, Drechslera hawaiiensis, Fusarium* spp., *Paecilomyces* spp., *Paracoccidioides brasiliensis, Penicillium marneffei,* Phaeohyphomycosis, *Pseudallescheria boydii, Sporothrix schenckii, Trichosporon beigelii, Ustilago* spp., *Zygomycetes* spp.

Parasites (Eosinophilic Meningitis)

Flukes: *Paragonimus westermani*, schistosomiasis, fascioliasis
Roundworms: *Angiostrongylus cantonensis, Gnathostoma spinigerum, Baylisascaris procyonis, Strongyloides stercoralis, Trichinella spiralis, Toxocara canis*
Tapeworms: Cysticercosis
Protozoa and free-living amoeba (noneosinophilic meningitis)
Acanthamoeba
Naegleria fowleri
Toxoplasma gondii (toxoplasmosis)

Vaccine-Associated

Measles
Mumps
Polio
Rabies
Vaccinia

Parameningeal Infection

Malignancy
Central nervous system tumor
Leukemia

Immune Diseases
Behçet syndrome
Lupus erythematosus
Sarcoidosis

Miscellaneous
Antimicrobial agents
Epidermoid, dermoid, other cysts
Foreign bodies (shunt, reservoir)
Heavy metal poisoning
Intrathecal injections (e.g., contrast media, antibiotics)
Kawasaki disease
Nonsteroidal anti-inflammatory drugs
Other drugs

*In other areas of the world, many other arboviruses are important.

associated with aseptic meningitis and other neurologic manifestations.* Similar outbreaks of aseptic meningitis caused by enterovirus 71 were reported in Malaysia, Japan, Hong Kong, and Australia.† Other enteroviruses involved in more recent outbreaks include echovirus 4 in Italy, Greece, Israel and Palestine, and Australia[147,216,220,261]; echovirus 6 in China[218]; echovirus 9 in Japan and regions of the United States[8,60]; echovirus 11 among institutionalized children in Israel[308]; echovirus 16 in Cuba[290]; echovirus 18 in Taiwan and Missouri[331,335,349]; echovirus 33 in New Zealand[166]; and coxsackievirus A9 in Latvia and China.[83,253] In the United States, the most common serotypes are coxsackie B1; echovirus 6, 9, and 18; and coxsackievirus A9, with echoviruses 9 and 30 being the most frequently identified etiologies of aseptic meningitis since 2003.[58,59,61,62,275,323]

Sharing seasonality with the enteroviruses, several arboviruses cause CNS disease in North America. Although encephalitis is the most recognizable manifestation of many of these infections, some arboviruses commonly are associated with aseptic meningitis as well.[63,132,275,279] Since the mid-1990s, outbreaks of West Nile virus (WNV) meningitis and encephalitis have occurred in Romania, Russia, and Israel.[73,258,332] First detected in the Western Hemisphere in 1999 in New York City, WNV subsequently spread across North America from the Atlantic to the Pacific coasts and into Canada and Mexico.[39,109,167,239,255] Between 1999 and 2008, almost 29,000 cases were reported in the United States, with more than 1100 deaths.[153,213] An estimated 1/150 infections results in severe neurologic illness, with meningitis as the primary manifestation in 16 to 40 percent of hospitalized patients.[175] Although the incidence of neuroinvasive disease increases with age, WNV is more likely to manifest as meningitis in children than in older adults and occurred in at least one quarter of the 150 pediatric cases diagnosed in the United States in 2002.[75,117,152,169,212] Even in regions with increased incidence of WNV, episodes of meningitis caused by enterovirus greatly outnumber those caused by WNV.[175]

Before the introduction of WNV, arboviruses accounted for approximately 5 percent of cases of aseptic meningitis in North America, with St. Louis encephalitis virus being the most common.[40,45,50,52] Infection with La Crosse encephalitis virus (a California encephalitis virus subtype) often resembles herpes encephalitis, but it may manifest as aseptic meningitis in children.[224] Unlike WNV, the majority of severe La Crosse encephalitis virus cases occur in children 15 years of age and younger, and in a study of 282 patients with La Crosse encephalitis virus infections in the Eastern United States from 2003 to 2007, 17 percent had aseptic meningitis.[63,144] Other California serogroup viruses, such as Jamestown Canyon virus and snowshoe hare virus, and other arboviruses, such as Colorado tick fever, result in aseptic meningitis more frequently than encephalitis.[132,275,313] Tick-borne encephalitis can manifest as aseptic meningitis in endemic areas. Tick-borne encephalitis virus cases were reported more recently in studies conducted in Slovenia and Sweden, and in mild cases, the clinical presentation was that of aseptic meningitis.[141,203,215]

Aseptic meningitis is an occasional manifestation of acute and recurrent genital infections with herpes simplex virus–2 (HSV-2).* In contrast to HSV-1 CNS infections, which without treatment usually are fatal, HSV-2 aseptic meningitis in otherwise immunocompetent patients is a benign, self-limited illness. Herpes family viruses other than HSV-1 and HSV-2 also are potential causes of aseptic meningitis. Although neurologic involvement in primary varicella-zoster virus (VZV) infections usually is encephalitis rather than benign meningitis, herpes zoster infection occasionally does present with concurrent meningitis.† VZV has been identified by PCR in the CSF of patients who had acute aseptic meningitis without cutaneous lesions, and meningitis associated with the VZV vaccine strain has been described.‡ One recent report detected VZV vaccine strain in a young patient with viral meningitis 11 years after vaccination.[245] A variety of neurologic disorders, including aseptic meningitis, are rare complications of Epstein-Barr virus infection.[110,119,137,317,334] Most noncongenital infections with cytomegalovirus in nonimmunocompromised patients are unrecognized; however, occasional instances of aseptic meningitis have been noted.[90-92,264,265]

The role of human herpesvirus–6 (HHV-6) in causing meningitis is unclear; although HHV-6 has been found in CSF samples from infants with meningitis, the virus also is detectable in the CSF of asymptomatic individuals.[12,42,361,365] Similarly, PCR identified HHV-7 in the CSF of six children with neurologic diseases, including aseptic meningitis, meningoencephalitis, facial palsy, vestibular neuritis, and febrile seizures.[259] The role of HHV-7 as a causative agent in aseptic meningitis remains to be determined.

Occasionally, meningitis or meningoencephalitis occurs as a manifestation of acute illness with HIV-1 infection.[18,145] Neurologic manifestations develop 3 to 6 weeks after primary infection at the same time as an infectious mononucleosis–like illness.

Lymphocytic choriomeningitis virus was an important historical cause of aseptic meningitis. In 1974, eight cases of aseptic meningitis caused by lymphocytic choriomeningitis virus were found in New York State.[93] Today, it is rarely recognized as a cause of meningitis, which is likely a result of both decreasing incidence of disease and decreased detection.§ Seroprevalence studies conducted over 2 decades ago found seroprevalence of 4.7 percent, whereas more recent studies show a much lower seroprevalence of 0.4 percent.[70,190] Nevertheless, physicians should be alert to the possibility in all situations of rodent (pet or wild) exposure and test appropriately. Encephalomyocarditis virus is another rodent virus that rarely is recognized in humans.[350] It is associated with a variety of neurologic manifestations, including aseptic meningitis.[121]

§References 9, 16, 19, 23, 30, 93, 226, 309.

Adenoviral types 1, 2, 3, 5, 6, 7, 12, 14, and 32 have been associated with meningitis and meningoencephalitis.* Although they occur infrequently, adenoviral CNS infections tend to be more severe than enteroviral infections. Rarely, aseptic meningitis has been noted during illnesses caused by influenza A viruses, including 2009 pandemic influenza (H1N1), influenza B, rhinoviruses, parainfluenza viruses, parvovirus B19 virus, rotaviruses, and coronaviruses.† Most infections with measles, rubella, and variola viruses that involve the CNS are encephalitic.[46,47,49,230]

In the prevaccine era, mumps virus was the agent responsible for the greatest number of cases of aseptic meningitis; today in the United States, use of vaccine has rendered mumps rare, although mumps outbreaks with associated cases of aseptic meningitis occur occasionally.[51,60] Aseptic meningitis and encephalitis resulting from administration of mumps vaccine have been noted in Canada, Brazil, Japan, and Europe.‡ The Leningrad 3, Urabe Am 9, and three Japanese strains of vaccine viruses have been implicated. In the United States, where the Jeryl Lynn vaccine strain has been used exclusively, the rate of encephalitis in vaccinees has been no higher than that of the observed background incidence of similar illness in the population.[45] A preliminary analysis of the Vaccine Safety Datalink project showed a possible increased risk for developing aseptic meningitis 8 to 14 days after receiving immunization with Jeryl Lynn mumps vaccine strain. A follow-up case-control evaluation of hospitalized cases failed to show an increased risk, however.[33]

Neurologic illness is a rare complication of measles, smallpox, polio, and rabies viral vaccines. In most instances, the illnesses are complex and severe, but occasionally, aseptic meningitis is the only manifestation.§ A case of aseptic meningitis caused by vaccine-derived poliovirus was reported in the Philippines in 2001.[56] It was in association with two pediatric cases of acute flaccid paralysis that occurred during the same time period. Viral isolates from all three patients revealed type 1 poliovirus derived from the Sabin vaccine strain.

Certain bacteria are important to recognize as etiologic agents in aseptic meningitis because the illnesses are treatable and early initiation of therapy is crucial. Of greatest importance is tuberculous meningitis. Early treatment of this illness nearly always results in complete cure, whereas diagnostic delay or inadequate treatment frequently results in permanent neurologic sequelae. Lyme disease, relapsing fever, brucellosis, leptospirosis, and rickettsial infections are illnesses acquired either directly or indirectly from animals, in which aseptic meningitis may be a part of the disease process.¶ *Mycoplasma pneumoniae* has been implicated as a causative agent of neurologic illness.[44,105,145,265,339] Pönkä[260] noted that 8/560 hospitalized patients with *M. pneumoniae* infections had aseptic meningitis and 18 had encephalitis or meningoencephalitis. Despite numerous case reports and case series, the role of *M. pneumoniae* is thought by some experts to be unknown.[32] *Mycoplasma hominis* and *Ureaplasma urealyticum* are rare causes of neonatal meningitis.[123,219,342,343] Meningitis and meningoencephalitis have been associated with *Chlamydia pneumoniae* infections.[13,139,304,318] Partially treated common bacterial meningitides are a common cause of meningitis in which cultures of CSF fail to grow organisms. Antigen detection systems, such as latex agglutination, can be useful in identifying the causative agents in some of these cases.

Numerous fungi and yeasts cause meningitis.[287] Although many fungal meningitides occur almost exclusively in immunocompromised patients, children and adults with normal immune status experience meningitis most commonly caused by *Blastomyces dermatitidis*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Cladosporium* spp., *Histoplasma capsulatum*, and *Paracoccidioides brasiliensis*.[22,116,222] In infants who are premature or younger than 1 month of age, *Candida albicans* is an important cause of meningitis and is associated with significant morbidity and mortality.[24,136,234]

Parasites occasionally cause aseptic meningitis. Eosinophilic meningitis is caused by *Angiostrongylus cantonensis*, a rat lungworm.* Aseptic meningitis caused by *A. cantonensis* has been observed on several islands in the Pacific, and the infection may be acquired by the consumption of freshwater shrimp.

A sterile CSF pleocytosis occurs in 12 to 13 percent of young infants with bacterial urinary tract infections[6,113,320] and in approximately one third of patients with Kawasaki disease who undergo lumbar puncture.[94,131] Numerous drugs and biologics have been implicated in aseptic meningitis.† Of most importance in pediatrics are trimethoprim-sulfamethoxazole and intravenous immunoglobulin. Other causes of aseptic meningitis are listed in Table 35-1.‡

EPIDEMIOLOGY

No unified epidemiologic pattern exists because so many different types of organisms cause aseptic meningitis. The epidemiology of the specific individual infectious agents or diseases is presented in detail in the various chapters of this book, and only a brief overview is presented here.

Because approximately 85 percent of all cases of aseptic meningitis are caused by enteroviral infections, the basic epidemiologic pattern of aseptic meningitis reflects these agents. In temperate climates, most cases occur in the summer and fall; infection with enteroviruses is spread directly from person to person, and the incubation period usually is 4 to 6 days. Epidemiologic considerations in aseptic meningitis caused by agents other than

enteroviruses depend markedly on season, geography, climatic conditions, animal exposures, and many other factors related to the specific pathogens.

CLINICAL MANIFESTATIONS

Aseptic meningitis has many causes (see Table 35-1), and clinical manifestations vary with the different diseases. In some instances, the signs and symptoms resulting from meningeal inflammation dominate the clinical illness, whereas in other instances the main signs and symptoms reflect other organ system involvement. Clinical manifestations in aseptic meningitis, regardless of etiology, also vary markedly by patient age.

Enteroviruses

Enteroviruses are the most common cause of aseptic meningitis, and they can be considered the prototype for a description of general clinical manifestations of aseptic meningitis.* Even among the enteroviruses, however, significant differences in clinical manifestations exist among the different viral types. Some general aspects of epidemic enteroviral aseptic meningitis are presented by viral type in Chapter 165.

The onset of illness generally is acute, although it may be insidious over the course of a week or so, or may be preceded by a nonspecific acute febrile illness of a few days' duration. Almost all children have fever, and most older children have headache, which most often is retroorbital or frontal in location. Photophobia is common. Temperature elevation varies, ranging from 38° to 40.5° C (100.4° to 105° F), and usually lasts approximately 5 days. Occasionally, fever is biphasic, with the initial elevation occurring before the onset of neurologic signs and symptoms. Anorexia, nausea, and vomiting are common, and abdominal pain and diarrhea also are reported frequently.

Meningeal signs (i.e., stiff neck and back, tightness of the hamstring muscles, and Brudzinski and Kernig signs) usually are present, but deep tendon reflexes usually are normal or hyperactive. Seizures occur occasionally, usually when concomitant high fever is present. Muscle weakness rarely is reported, but myalgia occasionally is noted. In young children, fever, irritability, and lethargy are the most common findings. Infants may be irritable and show resentment to handling, and the fontanelle may be tense.

Other manifestations of enteroviral infections also occur in children with aseptic meningitis. The most common is pharyngitis, which may occur during infection with all of the neurotropic enteroviral types. Rash occurs commonly, but varies by viral type. With echovirus 9 meningitis, 30 to 50 percent of children have rashes, whereas with echovirus 6, exanthem is rare. Cases of meningitis caused by enterovirus 71 and coxsackie A 16 frequently are accompanied by hand, foot, and mouth syndrome. Enanthem, pleurodynia, pericarditis, myocarditis, and conjunctivitis are other findings noted in children with enteroviral aseptic meningitis. Illness often is biphasic with fever, an interlude, then return of fever and neurologic manifestations.

CSF leukocyte counts vary from a few cells to a few thousand cells; the median is in the range of 100 to 500 cells/mm^3. The percentage of neutrophils also varies greatly. Initially, a predominance of neutrophils commonly occurs; later, CSF examinations show a decline in the percentage of neutrophils. The CSF protein usually is elevated mildly, and the glucose concentration usually is normal; rarely, hypoglycorrhachia is noted.

The duration of illness varies. Usually, disability because of neurologic involvement lasts 1 to 2 weeks.

Aseptic Meningitis Caused by Other Agents

Of 1478 pediatric WNV cases reported from 1999 through 2007, 30 percent were classified as West Nile neuroinvasive disease (WNND).[212] Unlike in older adults who often have encephalitis, most WNND in pediatric patients manifests as meningitis. Seizures occur more commonly in arboviral meningitides than in enteroviral illnesses of otherwise comparable severity.[149] The CSF findings generally are similar to those in enteroviral disease, although some reports suggest that neutrophils are more commonly seen with WNV than with other viral entities.[88,269] Examination of the CSF in mild cases of mumps often reveals pleocytosis, and mumps is one of the few viral infections that can cause hypoglycorrhachia. When neurologic disease caused by mumps is recognized, usually evidence of brain involvement is present.

Tuberculous meningitis usually has a gradual onset over the course of 2 to 3 weeks.[185,231,276] Initially, personality changes, irritability, anorexia, listlessness, and low-grade fever may be present, followed by signs of increased intracranial pressure, such as drowsiness, stiff neck, cranial nerve palsies, inequality of the pupils, vomiting, and seizures. Finally, coma, irregular pulse and respirations, and high fever occur. In fungal diseases, the course of meningitis is similar to the course of tuberculosis. In tuberculosis and several fungal meningitides, such as those caused by *C. immitis*, *H. capsulatum*, and *C. neoformans*, historical and radiographic evidence of pulmonary disease may be present.

Aseptic meningitis associated with *M. pneumoniae* is unique in that it frequently occurs a few days to 3 weeks after a respiratory illness (i.e., pharyngitis, bronchitis, or pneumonia).[140,210,305,333] Generally, the likelihood of a predominance of neutrophils is less in other aseptic meningitides, and low glucose levels are likely in parameningeal bacterial infections, partially treated bacterial meningitides, brain tumors, leukemic infiltration, *M. pneumoniae* infections, fungal infections, and tuberculosis.

Recurrent Aseptic Meningitis (Mollaret Meningitis)

In 1944, Mollaret[232] described three patients with recurrent aseptic meningitis whom he had observed over the

*References 3, 6, 10, 35, 54-57, 64, 87, 98, 115, 125, 138, 142, 147, 148, 154, 156, 165, 177, 180, 181, 195, 209, 270, 278, 283, 284, 286, 288, 301, 316, 321, 354.

course of 15 years. Subsequently, many other cases have been reported, and some cases have been noted in children.* The illness is characterized by recurrent attacks of fever with meningeal signs and symptoms. The attacks last several days and are separated by symptom-free periods lasting weeks or months. In addition to a lymphocyte-predominant pleocytosis, CSF samples obtained from certain patients contain large mononuclear cells (Mollaret cells). The disease remits spontaneously. HSV-2 has been identified by PCR or DNA probes in the CSF of most patients with recurrent meningitis.† Other viruses, such as HSV-1 and Epstein-Barr virus, and noninfectious causes, such as systemic lupus erythematosus, intracranial cysts, antibiotics such as amoxicillin, and environmental exposures, also have been identified as less frequent etiologies of recurrent meningitis.‡

DIFFERENTIAL DIAGNOSIS

Careful analysis of the history and epidemiologic circumstances may point toward one of the specific causes listed in Table 35-1. During the summer and autumn, the presence of pleurodynia, herpangina, or unexplained febrile eruptions in the community suggests the possibility of enteroviral infections. Acute paralytic disorders in other patients suggests poliomyelitis, enterovirus 71, or WNV. Exposure to mosquitoes and encephalitis in horses implicates certain arboviruses, and exposure to ticks may be suggestive of Lyme disease, relapsing fever, or rickettsial disease, depending on the geographic location and other symptoms of the illness. A history of swimming in waters contaminated by urine from infected animals and exposure to rats in urban slums suggest leptospiral infection. Knowledge of clear-cut exposure to or concurrent evidence of mumps or of one of the common exanthems is helpful in delineating the differential diagnosis. The association of pneumonia or other respiratory illness preceding aseptic meningitis strongly suggests the possibility of *M. pneumoniae* as the etiologic agent.

Most difficult from the diagnostic, therapeutic, and prognostic points of view are instances of incipient or partially treated bacterial (especially when caused by *Haemophilus influenzae*) or mycobacterial meningitis. The clinical findings; the dosage of antibiotic previously used; the spinal fluid smear, latex agglutination, or other rapid antigen identification test; the culture; and the glucose level may be helpful in diagnosing bacterial meningitis. The quantitative determination of C-reactive protein in the CSF also may be useful in differentiating bacterial from viral meningitis.[2,80,89,248,249] Lindquist and associates[211] found that the determination of CSF concentrations of lactate was the most useful test in differentiating bacterial from nonbacterial causes of meningitis. Studies suggest that the presence of tumor necrosis factor-α in the CSF is rare in viral infections, but common in bacterial disease.[7,103,128] When tuberculous meningitis is suspected, a careful evaluation of contacts, a careful examination of an appropriately stained smear from the pellicle of the CSF that was allowed to settle, and a positive tuberculin reaction or positive interferon-γ release assay may confirm the diagnosis. Because combined bacterial and viral infection has occurred, examinations of CSF should be repeated if any doubt exists. The possibility that the observed meningeal reaction is of neither viral nor bacterial origin must be considered. Finally, CNS tumor must be considered in the differential diagnosis, particularly if hypoglycorrhachia and prominent signs of increased intracranial pressure are present.[193]

SPECIFIC DIAGNOSIS

Obtaining a meticulous history is essential. The clinician must evaluate exposure of the patient in the past 2 to 3 weeks to illness in contacts; exposure to mosquitoes, ticks, and animals during recent vacations, picnics, and so on; awareness of illness in animals, especially horses and other Equidae, in the patient's environment; recent travel from the home area; recent injections or medications of any kind; and the possibility of accidental exposure to heavy metals.

The CSF must be examined carefully to exclude disorders that respond to specific therapy. Smears for bacteria, appropriate rapid antigen identification tests, and cultures of the CSF are mandatory; the history and clinical findings may indicate the need for performing acid-fast stain and culture of the sediment for mycobacteria. Other circumstances may indicate the need for excluding fungal or protozoal infection; atypical cells may require cytopathologic study to exclude neural neoplasms, which may manifest acutely.

The introduction of PCR has facilitated the etiologic diagnosis of CNS viral infections, particularly infections caused by enteroviruses and herpesviruses.[127,164,178,292,329,363] PCR detects enterovirus in the CSF more rapidly than does cell culture and has been shown to shorten the duration of hospitalization for children with meningitis, reducing costs.[240,293,315] Enterovirus PCR tests do not detect parechoviruses; specific PCR testing for parechoviruses should be ordered in the appropriate population (especially children younger than 3 years).

PCR is the test of choice for detecting CNS infections caused by HSV, and molecular techniques also have been used to identify in CSF such causes of meningitis and meningoencephalitis as VZV, HHV-6, parvovirus B19, and rotavirus.[21,172,192,337]

For many arboviruses, serologic examination is more sensitive than molecular methods, especially for arboviruses that have a short period of viremia and presence in the CSF such as WNV. Molecular methods may have a complementary role, as in one study in which WNV PCR analysis had a 57 percent sensitivity and 100 percent specificity.[74,196]

In any patient suspected to have viral meningitis, spinal fluid, serum, feces, and throat swabs should be collected and either held in hospital laboratory or sent to a public health laboratory with viral diagnostic services. An additional serum specimen should be collected 10 to 21 days later so that paired sera can be examined for

*References 38, 77, 78, 157, 256, 314, 325.
†References 20, 77, 104, 194, 256, 291, 322, 325, 336.

antibody titer increases. This pairing is particularly useful in arboviral, lymphocytic choriomeningitis, encephalomyocarditis, leptospiral, borrelial, rickettsial, mycoplasmal, and toxoplasmal infections. Although these studies may not provide an immediate diagnosis, they may give early warning of a specific epidemic, and they are useful for prognostication, particularly in very young infants.

TREATMENT

Hospitalization usually is necessary because of the possibility of treatable bacterial disease, the frequent need for fluid therapy for dehydration, and sometimes for analgesics. Headache and hyperesthesia are treated with rest; analgesics; and a reduction in room light, noise, and visitors. Antipyretics are recommended for fever. Using acetaminophen rather than aspirin is prudent because of the risk for developing Reye syndrome associated with the latter antipyretic. Codeine, morphine, and the phenothiazine derivatives often are used for pain and vomiting but are rarely necessary in children and should be avoided because they may induce misleading signs and symptoms. The investigational antiviral drug pleconaril has been shown effective in the treatment of enteroviral meningitis; however, this drug presently is unavailable.[96,280,281,282] Treatment for illnesses such as tuberculous meningitis, fungal meningitides, and other illnesses for which specific therapies are available is covered in specific chapters of this book.

Several weeks after the patient has apparently recovered, a careful neuromuscular assessment should be conducted to ensure that muscular weakness is not a sequela. Bilateral audiometry is recommended, especially when mumps virus was involved.

PROGNOSIS

The prognosis in aseptic meningitis depends on the etiology. Some illnesses have an ominous prognosis (i.e., tuberculous meningitis, parameningeal infections, rickettsial infections), but patients usually do well if appropriate specific therapy is instituted early in the course of the illness. In *C. immitis* meningitis, the prognosis for cure is guarded even with early optimal therapy.

In enteroviral and other viral meningitides, children usually recover completely. Some patients complain of fatigue, irritability, decreased ability to concentrate, muscle pain, muscle weakness and spasm, and incoordination for several weeks after an acute illness. Although the outcome of enteroviral meningitis most often is without residual, some infants who have enteroviral meningitis in the first few months of life have an increased risk for altered language development.[25,355] Formally evaluating such children at age 3 to 6 years is important.

PREVENTION

The universal use of polio and mumps vaccines in children clearly is effective in controlling these two diseases. Control of insect vectors by suitable spraying methods and eradication of insect breeding sites is important in the control of many arboviruses. The control of animal vectors such as mice and rats alters the incidence of infections with lymphocytic choriomeningitis and encephalomyocarditis viruses.

associated meningeal inflammation, thus representing an overlap with meningoencephalitis. For the purposes of this chapter, these terms are used interchangeably. The diagnosis of encephalitis can be established only by the microscopic examination of brain tissue or the recovery of a neurotropic agent. In clinical practice, however, the diagnosis is presumptive and frequently based on clinical features.

Encephalitis is often classified as primary or as postinfectious or parainfectious. Primary encephalitis is an illness in which encephalitis is the major manifestation. Symptoms are caused by direct invasion and replication of an infectious agent in the central nervous system (CNS), resulting in objective clinical evidence of cerebral or cerebellar dysfunction. Postinfectious or parainfectious encephalitis occurs after or in combination with other illnesses that are not CNS illnesses or after a vaccine or other product has been administered. Manifestations may be mediated immunologically. Clinical symptoms can result from noninfectious causes and are often indistinguishable from those of infectious encephalitis.

Frequently, when encephalitis occurs, other regions of the nervous system, such as the spinal cord (myelitis), nerve roots (radiculitis), and nerves (neuritis), also are involved. When neurologic clinical findings suggest encephalitis but inflammation of the brain has not occurred (e.g., influenza encephalopathy), the condition is identified by the less-specific term *encephalopathy.*

HISTORY

Rabies encephalitis was recognized in ancient times in Europe and Asia.[224] In AD 100, Celsus noted the relationship of animal rabies to human disease. "Sleeping sickness" associated with epidemic influenza was noted early in the 18th century.[445] For the past 100 years, epizootics of encephalitis in equine animals have been observed in the United States; and in 1933, St. Louis encephalitis virus was isolated from the brains of humans dying of epidemic encephalitis.[303,329] Meningoencephalitis was recognized at the beginning of the 20th century as a complication of mumps.[136] Nonpolio enteroviruses have been known for the past 60 years to be a cause of encephalitis; during the same period, more than 400 zoonotic arthropod-borne viruses have been discovered; and of these, 100 or more cause encephalitis in humans.[33] In countries where vaccines are widely available there has been a decline in vaccine-preventable neurologic complications from measles, mumps, and rubella. However, there has been a continually expanding list of emerging or reemerging pathogens, including *Balamuthia mandrillaris*, *Baylisascaris procyonis*, parechoviruses, Nipah virus, and Chandipura virus. Moreover, there has been expansion of certain agents into geographic regions.[177] West Nile virus, for instance, has expanded its geographic range from Africa to North and South America, Europe, the Middle East, western Asia, and Australia.[184] Japanese encephalitis virus has spread into India, Nepal, and northern Australia.[402] Chikungunya is the most recent example of a striking geographic virus expansion with outbreaks in the Indian Ocean and subsequent spread to India and Europe. Simultaneously, the neurologic complications from Chikungunya appear to be increasing as well.[19]

ETIOLOGY

The many causes of encephalitis include both infectious and noninfectious entities. The infectious causes include viruses, bacteria, fungi, and parasites. Etiologic agents of acute encephalitis, meningoencephalitis, or illnesses that clinically resemble encephalopathy are listed in Table 36-1. Many of the infectious agents or diseases are discussed more fully and are referenced more completely elsewhere in this book (see Index).

Despite extensive testing and evaluation, the causes of many cases of encephalitis remained unexplained in recent prospective studies.[163,247,353] During the first seven years of the California Encephalitis Project, 1570 patients were identified who met the case definition of having encephalitis (immunocompetent patients older than 6 months of age hospitalized with at least 24 hours of encephalopathy and one or more of the following characteristics: fever, seizure, focal neurologic findings, or electroencephalographic [EEG] or neuroimaging findings consistent with encephalitis). A confirmed or probable agent was identified in only 251 (16%) cases; of these agents, 69 percent were viral, 20 percent were bacterial, 3 percent were prion, 3 percent were parasitic, and 1 percent were fungal. An additional 13 percent had a possible cause identified, and a noninfectious cause was identified in 8 percent of cases.[164] Similar percentages of "unknown" causes are seen in studies across the globe—in Australia from 1990 to 2007, 69.8 percent unknown; in England from 1989 to 1998, 60 percent unknown; and in another study in the United States, 60 percent unknown.[112,215,242]

Viruses

Some types of viral encephalitides are an uncommon complication of a relatively common infection, such as enteroviruses and herpesviruses, whereas others are clinical manifestations of newly emerging or rare pathogens such as Hendra virus, lymphocytic choriomeningitis virus, Chikungunya, or rabies.

Enteroviruses and Parechoviruses

Enteroviruses and parechoviruses are small, nonenveloped single-stranded RNA viruses within the Picornaviridae. Encephalitis is a rare complication of enteroviruses, but because enteroviruses are so common and estimated to cause 10 to 15 million illnesses per year in the United States they are a leading cause of encephalitis, particularly in children.[410] Of encephalitis cases with a cause identified, enteroviruses comprise 10 to 15 percent of cases.[308] Enteroviruses are now the leading viral cause of neurologic disease in children in the United States, and

Text continued on p. 499

TABLE 36-1 **Encephalitis (with a Focus on Immunocompetent Patients and Pathogens in the United States)**

Etiology	Association with Encephalitis	Epidemiology	Clinical and Laboratory Hallmarks	Recommended Tests and "Pitfalls"
Viruses				
Adenovirus	Mostly anecdotal data; unclear neurotropic potential	Sporadic; children and immunocompromised persons at greatest risk	Respiratory symptoms common	Viral culture or PCR from respiratory site, CSF, or brain tissue
Eastern equine encephalitis virus	Proven neurotropic potential, but uncommon	Atlantic and Gulf U.S. states	Subclinical to fulminant; 50%-70% mortality	Serology
Enteroviruses (include coxsackieviruses and enterovirus 71)	Most common cause of encephalitis in pediatric population	Highest incidence in late summer and early fall but can occur year round; large outbreaks of enterovirus 71 infection in Asia have occurred.	Aseptic meningitis most common but also encephalitis; hand, foot and mouth rash may be present; enterovirus 71 can cause rhomboencephalitis.	CSF PCR single best test but not always sensitive; to increase sensitivity of detection add serum/plasma, throat PCR or culture.
Epstein-Barr virus	Relatively common	During acute infection	Infectious mononucleosis during acute infection, cerebellar ataxia, sensory distortion ("Alice-in-Wonderland" syndrome)	Serology and CSF PCR. Beware of PCR false-positive results (detection of low levels may represent latent infection) and false-negative results (not all cases are CSF positive).
Hendra virus	Less common	Endemic in Australia; associated with equine exposure	Nonspecific	Contact local health department or Special Pathogens Branch at CDC.
Hepatitis C	Mostly anecdotal data; unclear neurotropic potential; neurologic symptoms may be related to vasculitis.	Hepatitis C–seropositive patients		CSF PCR
Herpes B virus	Proven neurotropic potential; rare	Transmitted by bite of Old World macaque	Vesicular eruption at site of bite followed by neurologic symptoms, including transverse myelitis	Culture and PCR of vesicles, CSF; contact CDC or Dr. Julia Hilliard.
Herpes simplex virus (HSV) types 1 and 2	Relatively common	HSV type 1 accounts for 5%-10% of encephalitis; typically a reactivation disease, HSV type 2 occurs in neonates.	Temporal lobe seizures (apraxia, lip smacking), olfactory hallucinations, behavioral abnormalities, but children often have extratemporal lesions as well	CSF PCR single best test, but false-negative results can occur; if HSE strongly suspected, repeat lumbar puncture in a few days and recheck HSV PCR and intrathecal antibodies.
Human herpes virus–6	Unknown, especially owing to difficult interpretation of CSF PCR false-positive results	Young children (≤2 yr) or immunocompromised patients, particularly bone marrow transplant recipients	May be associated with "roseola rash"	CSF PCR. Beware of false-positive findings due to chromosomal integration and latent infections.
Human metapneumovirus	Anecdotal evidence only	Newly described; almost exclusively in children	Often with associated respiratory symptoms	Respiratory tract PCR (most CSF PCR negative)
Influenza virus	Unclear neurotropic potential; good data to support flu-associated encephalopathy but unclear if encephalitis and unclear mechanism	Neurologic complications occur; sporadically reported during influenza seasons; higher numbers reported in Japan and Southeast Asia	Upper respiratory tract symptoms CSF often acellular in 10% with bilateral thalamic necrosis	Respiratory tract culture, PCR, or rapid antigen. CSF and brain PCR infrequently positive

Japanese encephalitis virus	Relatively common (but only in endemic areas)	Mosquito-borne; most common worldwide cause of encephalitis; endemic throughout Asia; vaccine preventable	Seizures, parkinsonian features, acute flaccid paralysis variably seen. MRI classically shows thalamic and basal ganglia involvement	CSF and serum antibodies
La Crosse virus	Relatively common	Mosquito-borne; endemic in U.S. East and Midwest; highest incidence in school-aged children	Varies from subclinical illness to seizures and coma	CSF and serum antibodies
Lymphocytic choriomeningitis virus	Rare	Highest incidence in fall and winter; rodent exposure	One of few viral causes of hypoglycorrhachia	Serology
Measles virus	Less common in countries where vaccine is routinely used	Vaccine preventable; measles inclusion body encephalitis onset 1-6 mo after infection; SSPE can manifest >5 years after infection.	Measles encephalitis nonspecific. SSPE has a subacute onset with progressive dementia, myoclonus, seizures, and, ultimately, death. EEG changes are often diagnostic.	Acute form: measles IgM SSPE: measles IgG in CSF and serum
Mumps virus	Less common	Vaccine preventable; used to be leading cause of encephalitis-meningitis, now rarely seen	Parotitis, orchitis, hearing loss; one of few viral causes of hypoglycorrhachia	Serology, throat swab PCR, CSF culture or PCR
Murray Valley encephalitis virus	Less common	Highest incidence in Aboriginal children in Australia and New Guinea	Nonspecific presentation; case fatality 15%-30%	Serology (may cross react with other flaviviruses)
Nipah virus	Less common	Epidemics in Southeast Asia; contact with pigs	Myoclonus, dystonia, pneumonitis	Serology (Special Pathogens Branch, CDC)
Parainfluenza 1-4	Unknown neurotropic potential; anecdotal evidence	Worldwide	Associated with respiratory symptoms	Respiratory DFA or PCR; CSF PCR rarely positive
Parechoviruses	Proven neurotropic potential but frequency unknown	Children <3 yr	In young infants periventricular white matter changes resemble hypoxic ischemic encephalopathy.	Parechovirus PCR (enterovirus PCR will not detect)
Parvovirus B19	Anecdotal evidence only	Sporadic cases	Variably associated with rash	IgM antibody, CSF PCR
Powassan virus	Less common	Tick-borne; endemic to New England, Canada	Nonspecific	Serology
Rabies virus	Uncommon in developed countries; relatively common in Africa, Asia, South America	Vaccine preventable; most common vector is bat (bites often unrecognized); dogs important source in developing countries; worldwide distribution	Paresthesia at site of bite. Furious form: hydrophobia, agitation, delirium, autonomic instability, coma Paralytic form: ascending paralysis in 30% Two forms sometimes overlap.	Multiple tests and assays needed for antemortem testing: antibodies (serum, CSF), PCR of saliva or CSF, IFA of nuchal biopsy or CNS tissue. Coordinate testing with health department.
Rotavirus	Correlation with seizures in young child but unclear association with encephalitis	Typically children; winter; vaccine preventable	Usually with diarrhea	Stool antigen, CSF PCR (CDC)

Continued on following page

TABLE 36-1 **Encephalitis (with a Focus on Immunocompetent Patients and Pathogens in the United States)** (Continued)

Etiology	Association with Encephalitis	Epidemiology	Clinical and Laboratory Hallmarks	Recommended Tests and "Pitfalls"
Rubella virus	Less common in countries where vaccine is routinely used	Vaccine preventable	Neurologic findings typically occur at same time as rash and fever	Serology, CSF antibodies
St. Louis encephalitis virus	Relatively common	Mosquito-borne; endemic to western U.S.; occasional outbreaks in central/eastern U.S.; highest incidence in adults >50 yr	Tremors, seizures, paresis, urinary symptoms, SIADH variably present	Serology (cross reacts with other flaviviruses)
Tick-borne encephalitis virus	Relatively common in affected geographic areas	Vaccine-preventable; transmitted via tick or ingestion of unpasteurized milk; endemic to Asia, Europe and areas of former Soviet Union	Weakness ranging from mild paresis to acute flaccid paralysis	Serology
Vaccinia	Less common	Primarily associated with vaccination	Vaccinia rash (localized or disseminated)	CSF antibodies, serum IgM (natural infection)
Venezuelan equine encephalitis virus	Less common	Central and South America; sometimes in U.S. border states (Texas, Arizona)	Myalgias, pharyngitis, upper respiratory tract infection variably present	Serology, viral cultures (blood, oropharynx), CSF antibody
Varicella zoster virus	Relatively common	Acute infection (chickenpox) or reactivation (shingles)	Vesicular rash (disseminated or dermatome), cerebellar ataxia, large vessel vasculitis	DFA or PCR of skin lesions, CSF PCR, serum IgM (acute infection)
Western equine encephalitis virus	Less common	Onset in summer and early fall; western U.S. and Canada, Central and South America	Nonspecific	Serology
West Nile virus	Relatively common	Mosquito-borne; emerging cause of epidemic encephalitis in U.S., Europe; endemic in Middle East; highest incidence in adults >50 yr; documented transmission through organ and blood	Weakness and acute flaccid paralysis, tremors, myoclonus, parkinsonian features; MRI shows basal ganglia and thalamic lesions.	CSF IgM, serum IgM/IgG, paired serology (cross reactivity with West Nile virus and SLE)
Bacteria				
Bartonella henselae (and other *Bartonella* spp.)	Relatively common	Often occurs after scratch or bite from kitten	Encephalopathy with seizures (often status epilepticus); peripheral lymphadenopathy. CSF is usually paucicellular.	Serology (acute usually diagnostic), PCR of lymph node; CSF PCR rarely positive
Borrelia burgdorferi	Less common	Tick-borne infection; in U.S. mostly in New England and eastern Mid-Atlantic states	Facial nerve palsy (often bilateral), meningitis, radiculitis; may be associated with or follow erythema migrans rash.	Serology (serial EIA and Western blot), CSF antibody index, CSF PCR
Chlamydia spp.	Anecdotal evidence only	Associated with *C. psittaci* and *Chlamydophila pneumoniae*	Often with associated respiratory symptoms	NP swab, respiratory, or CSF PCR
Coxiella burnetti	Less common	Animal exposures, particularly placenta and amniotic fluid	Flulike symptoms	Serology

Ehrlichia /Anaplasma	Relatively common	Tick-borne bacteria causing human monocytic and human granulocytic ehrlichiosis (HME, HGE) respectively; HME endemic to southern and central U.S.; HGE endemic to northeastern U.S. and Midwest	Acute onset of fever and HA. Rash seen in <30% of cases. Leukopenia, thrombocytopenia, and elevated LFTs frequent manifestations	Morulae in white blood cells, PCR of whole blood, serology (seroconversion may occur several weeks after symptoms)
Mycoplasma pneumoniae	One of most frequently identified agents in case series but mostly anecdotal evidence	Worldwide distribution	Respiratory symptoms variably present, but pneumonia rare. Often with white matter involvement consistent with ADEM	PCR of NP swab or respiratory culture, serum IgM; CSF PCR rarely positive
Mycobacterium tuberculosis	Relatively common	Most common in developing countries; disease of very young and very old or immunocompromised	Subacute basilar meningitis, lacunar infarcts, hydrocephalus. CSF often with low glucose, high protein levels. Pulmonary findings often associated	CSF AFB smear, culture, PCR, respiratory cultures highly suggestive
Rickettsia rickettsii	Relatively common in affected geographic areas	Tick-borne infection in North America; highest incidence in southeast and south central U.S.	Acute onset of fever and headache. Petechial rash in 85% of cases beginning 3 days after onset of symptoms	Serology (seroconversion may occur several weeks after symptoms), PCR or IHC on skin biopsy of rash
Treponema pallidum	Rare (especially in pediatrics)	Sexually transmitted disease; meningoencephalitis in early disseminated disease; progressive dementia in late disease	Protean manifestations including temporal lobe focality (mimics HSV), general paresis, psychosis, dementia	CSF VDRL (sensitive but not specific), serum RPR with confirmatory FTA-ABS
Tropheryma whippelii	Rare (especially in pediatrics)		Progressive subacute encephalopathy, oculomasticatory myorhythmia pathognomonic. Variable enteropathy, uveitis	CSF PCR, PAS-positive cells in CSF, small bowel biopsy
Protozoa				
Acanthamoeba spp.	Less common; more common in immunocompromised	Worldwide, inhalation of wind-blown soil	Subacute progressive	Contact CDC/Parasitology.
Balamuthia mandrillaris	Less common	Worldwide (but most case reports in United States and South America), inhalation of wind-blown soil	Subacute progressive disease characterized by space-enhancing lesions, often with cranial nerve palsies and hydrocephalus (similar to tuberculosis)	Serology (research laboratories), brain histopathology, CDC laboratories Contact CDC/Parasitology for testing.
Naegleria fowleri	Less common	Summer; swimming or diving in brackish water or poorly chlorinated pools	Anosmia, progressive obtundation; CSF resembles bacterial meningitis, but sterile.	Mobile trophozoites on wet mount of warm CSF, brain histopathology

Continued on following page

TABLE 36-1 **Encephalitis (with a Focus on Immunocompetent Patients and Pathogens in the United States)** (Continued)

Etiology	Association with Encephalitis	Epidemiology	Clinical and Laboratory Hallmarks	Recommended Tests and "Pitfalls"
Toxoplasma gondii	Rare in normal hosts	Worldwide; cats definitive hosts but humans often infected via consumption of undercooked meats, unwashed produce		
Helminths				
Angiostrongylus cantonensis	Most common cause of eosinophilic meningitis worldwide; rare in United States	In the U.S. in Louisiana and Hawaii; South Pacific, Asia, Australia and Caribbean	Meningitis or encephalitis; eosinophils in CSF; also associated with eosinophilic pneumonitis	Identification of worm in tissues
Baylisascaris procyonis	Less common	North America, Europe, and Asia; pica, particularly near raccoon latrines	Obtundation, coma; significant CSF and peripheral eosinophilia	CSF and serum antibodies; contact CDC/Parasitology for testing.
Gnasthostoma spinigerum	Relatively common in affected geographic areas	Southeast Asia, some areas of South/Central America; undercooked freshwater fish, chicken, or pork; also reported with reports of ingestion of frogs/snakes	Eosinophilic myeloencephalitis; can cause intermittent symptoms for 10-15 years because larvae are long lived	Identification of worm in tissues
Fungi				
Coccidioides spp.	Relatively common	Southwest U.S., northern Mexico, areas of Central and South America	Neurologic manifestations are result of disseminated disease; more often meningitis than encephalitis. CSF eosinophils sometimes seen	CSF fungal culture (but need to alert lab); CSF and serum antigen and antibody. EDTA-heat–treated antigen increases sensitivity of CSF and serum.
Histoplasma capsulatum	Relatively common	Eastern and central U.S., especially Mississippi, Ohio and Missouri River valleys. Grows on mold, bird, and bat droppings; especially found in caves, barns, or excavation areas	Neurologic manifestations are result of disseminated disease.	CSF fungal culture; CSF and serum antigen and antibody. EDTA-heat–treated antigen increases sensitivity of CSF and serum. Urine antigen
Blastomyces dermatitidis	Relatively common	Southeast, central, and midwestern U.S.; also in Canada, Africa, and India	Neurologic manifestations are result of disseminated disease.	CSF fungal culture; CSF and serum antigen and antibody. EDTA-heat–treated antigen increases sensitivity of CSF and serum.

ADEM, acute demyelinating encephalomyelitis; *AFB,* acid-fast bacilli; *CDC,* Centers for Disease Control and Prevention; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *DFA,* direct fluorescent antibody test; *EDTA,* ethylenediaminetetraacetic acid; *EEG,* electroencephalogram; *EIA,* enzyme immunoassay; *FTA-ABS,* fluorescent treponemal antibody absorption test; *HA,* hemagglutination assay; *IFA,* indirect fluorescent antibody test; *IHC,* immunohistochemistry; *LFTs,* liver function tests; *MRI,* magnetic resonance imaging; *NP,* nasopharyngeal; *PAS,* periodic acid–Schiff; *PCR,* polymerase chain reaction; *RPR,* rapid plasma reagin; *SIADH,* syndrome of inappropriate secretion of antidiuretic hormone; *SLE,* systemic lupus erythematosus; *SSPE,* subacute sclerosing panencephalitis; *VDRL,* Venereal Disease Research Laboratory.

they are a major cause of encephalitis.* Of the 1750 patients with encephalitis enrolled in the California encephalitis project, enteroviruses were the leading causative agent.[175] Several enterovirus types have been associated with encephalitis: coxsackieviruses A2, A4 to A7, A9, A10, A16, A21 and B1 to B5; echoviruses 1 to 9, 11 to 25, 27, 30, and 33; and enteroviruses 71, 75, 76, and 89. In 1998, an extensive epidemic of enterovirus 71 disease occurred in Taiwan.† Outside the United States, outbreaks of enterovirus 71 have been observed, often with neurologic manifestations and relatively high morbidity and mortality.[277] Manifestations of illness in this epidemic varied, and many children had severe neurologic events, including meningitis, encephalitis, cerebellitis, and polio-like syndrome. In particular, numerous children had brain stem encephalitis, with many fatalities occurring.

The first two parechoviruses characterized, formerly echovirus 22 and echovirus 23, were originally described as enteroviruses. To date, 16 genotypes of parechovirus have been characterized.[92] As a group, parechoviruses can cause similar clinical diseases as enteroviruses, including respiratory, gastrointestinal, and sepsis-like syndromes and CNS infections. Neonates and young children have more severe clinical disease than older children. Parechoviruses 1 and 2 are most often associated with respiratory and gastrointestinal infections, but acute flaccid paralysis and encephalitis have occasionally been associated with parechovirus 1 (when formerly classified as echovirus 22).[140] Parechovirus 3 has been associated with sepsis, meningitis, and encephalitis and during the neonatal period has been associated with white matter changes, often suggestive of hypoxic-ischemia injuries.[43,188,195,437] The relative frequency of parechovirus infections is unknown, especially in neurologic illnesses, because these viruses are often difficult to grow and molecular testing for enteroviruses would not have detected parechoviruses.

Herpesviruses

Neurologic manifestations of herpesviruses are uncommon complications, but, like enterovirus infections, herpesvirus infections are common. Indeed, as a group the herpesviruses are among the most frequently identified agents responsible for viral encephalitis.[172,215,287,432] Herpes simplex encephalitis is the most common cause of sporadic fatal encephalitis in the United States, with approximately one third of cases occurring in patients younger than age 20 years but older than 6 months and with approximately half occurring in patients older than age 50 years.[303,366,431,451] Molecular analyses of paired oral or labial and brain sites have indicated that herpes simplex encephalitis can be the result of a primary infection, a reactivation of latent herpes simplex virus, or a reinfection by a second herpes simplex virus.[453] Although herpes simplex virus type 2 is a leading cause of severe and frequently fatal encephalitis in neonates,[452] type 1 is the usual cause in older children.* Meningitis is the most frequent neurologic sequela of herpes simplex virus type 2 genital infection outside the neonatal period but rarely can cause encephalitis.

Other herpesviruses, including varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, and human herpesvirus–6, can also cause encephalitis.[370] Encephalitis can occur in association with primary infection with varicella-zoster virus (chickenpox) or with endogenous recurrent disease (herpes zoster).† In a study in Finland of more than 3000 patients with acute CNS infections of suspected viral origin, varicella-zoster virus constituted 29 percent of all confirmed or probable etiologic agents.[251] In chickenpox, the rate of encephalitis is approximately 0.3 per 1000 cases[61] and the case-fatality rate is approximately 17 percent.[346] Of patients with herpes zoster, 0.5 to 5 percent have encephalitis.[223] This complication occurs more commonly in immunocompromised patients.

Epstein-Barr virus encephalitis occurs in less than 1 percent of cases, and most patients with Epstein-Barr virus encephalitis are adolescents and young adults. Patients typically present 1 to 3 weeks after the onset of mononucleosis syndrome, but encephalitis may be the presenting complaint in Epstein-Barr virus infection.‡ Caruso and associates[57] reported five children with subacute and chronic neurologic deficits associated with apparent primary Epstein-Barr virus infections. Severe chronic involvement of the brain is a common finding in congenital cytomegalovirus infection.[191] Encephalitis caused by acquired cytomegalovirus infection is uncommon and usually occurs in immunocompromised children.[180,203,393]

Human herpesvirus–6 is an important cause of acute febrile illness and roseola infantum in young children and is commonly associated with febrile convulsions.[133] Encephalitis is a rare complication of this infection in children with and without roseola.§ Human herpesvirus–6 increasingly has become recognized as an important cause of encephalitis in immunocompromised, posttransplant patients, occasionally manifesting as severe amnesia after they have undergone bone marrow transplantation.¶ Human herpesvirus–7 has also been implicated as a causative agent in encephalitis.[331,344,424,444]

Arboviruses

More than 400 different arboviruses exist, and detailed information about illnesses caused by specific types in various areas of the world is provided in Chapters 171, 174, 175, 189, and 190.[33,203,234] Arboviruses that are endemic to the United States and have been associated with encephalitis include eastern equine, western equine, Venezuelan equine, St. Louis, Powassan, West Nile, California serogroup viruses including La Crosse and Jamestown canyon, and Colorado tick fever. Historically,

arboviruses have been cited as one of the most common causes of encephalitis; however, recent studies found arboviruses to be relatively uncommon in the pediatric age group in the United States.[164,242]

First detected in the Western Hemisphere in 1999 in New York City, West Nile virus subsequently spread across North America from the Atlantic to the Pacific coasts and into Canada and Mexico.* Between 1999 and 2008, almost 29,000 cases of West Nile virus were reported in the United States, with more than 1,100 deaths.[200,279] An estimated 1 in 150 infections results in severe neurologic illness, and, although the incidence of neuroinvasive disease increases with age, West Nile virus has been responsible for encephalitis in young children and adolescents, occurring in 37 percent of the 443 pediatric cases diagnosed in the United States between 1999 and 2007.[97,149,199,278] Although West Nile virus was the most common cause of neuroinvasive arboviral disease in the United States in 2010, the most common cause among children was La Crosse virus.[81,189,333,360,380] Of all North American causes of arboviral encephalitis, eastern equine encephalitis virus results in the most severe disease and has the highest case-fatality rate, particularly among infants and children.[365]

Outside the United States, dengue is the most common mosquito-borne viral disease in the world, responsible for 50 to 100 million infections and 25,000 deaths each year.[162] In 2009 and 2010, 89 cases of dengue virus occurred in Key West, Florida.[78,171] With the exception of a few cases that occurred along the Texas-Mexico border, the cases in Florida represented the first local transmission of dengue virus in the continental United States since 1946.[67,68] Although encephalopathy is a well-reported neurologic complication of dengue fever, there has been increasing evidence that encephalitis with direct neuronal infiltration by dengue virus occurs.[46,436] Japanese encephalitis virus, also a mosquito-borne flavivirus, although not quite as common as dengue, is the most important cause of epidemic encephalitis worldwide, with an estimated 35,000 to 50,000 cases and 10,000 deaths annually.[400,402,428] Most cases occur in Southeast Asia, China, and the Indian subcontinent.[401]

Chikungunya, a mosquito-borne arbovirus of the Togaviridae, was first isolated in 1953 and has caused outbreaks in sub-Saharan Africa, India, and Southeast Asia.[342,433] In 2005 to 2006, an outbreak occurred on the island of Réunion, a French territory in the Indian Ocean involving 266,000 cases, which represented more than one third of the island's population. The epidemic subsequently spread to the Indian subcontinent, where 1.4 million cases were reported in 2006. Although neurologic features due to Chikungunya are rare, encephalitis has been diagnosed in the United States among travelers returning from endemic areas.[74,261,363,396] Tick-borne encephalitis, as the name implies, is transmitted by ticks and is caused by a group of tick-borne enteroviruses in the Flaviviridae. Within this group there are subtypes, including European or Western tick-borne encephalitis virus, Siberian tick-borne encephalitis virus, and Russian Spring-Summer encephalitis virus (a.k.a. Far Eastern tick-borne encephalitis virus). These viruses are found in Asia, parts of Europe, and areas of the former Soviet Union.

Vaccine-Preventable Viruses

Prior to the widespread availability of vaccines in the United States, measles, mumps, and rubella were a common cause of encephalitis. Although still occurring elsewhere in the world, including Europe,* measles is now a relatively rare occurrence in the United States.[76] Approximately 30 million cases of measles occur each year worldwide. Encephalitis occurs uncommonly, at a rate of 0.74 per 1,000 cases of measles; the case-fatality rate is 14 percent. Subacute sclerosing panencephalitis, an indolent and progressive form of encephalitis, generally occurs many years after the initial infection. Before the use of mumps vaccine became widespread, this virus was the leading cause of meningoencephalitis in the United States. Today, mumps is rare, although extensive mumps outbreaks with associated cases of encephalitis occurred in 2006.[73] The incidence of encephalitis among individuals with mumps is approximately 3 per 1,000 cases; the case-fatality rate is 1.4 percent.[65] Neurologic involvement is a common manifestation of congenital rubella virus infection,[192] and encephalitis is a rare complication of noncongenital disease.[84,186,267,306] Some data suggest a rate of encephalitis in rubella between 1 per 5,000 and 1 per 10,000 cases.[63] In the prevaccine era, the encephalitis rate in one epidemic in 1964 was 1 per 5,000 cases, and in another epidemic in 1942, it was 1 per 6,000 cases.[290,388] Smallpox (variola virus infection), before its worldwide eradication, was a rare cause of encephalitis. Human rabies is uncommon in the United States, but approximately 55,000 cases occur worldwide primarily in Asia, Africa, and Latin America.[243] Since the early 1970s, approximately two cases of rabies have occurred per year in the United States and approximately 50 percent of the cases have occurred in children and teenagers.[8,64,66]

Rare and/or Newly Emerging Viruses

Lymphocytic choriomeningitis virus is an arenavirus acquired from infected rodents. It was previously a relatively common cause of encephalitis in the United States but now is rarely recognized, except for occasional outbreaks.[35] Clusters of cases of lymphocytic choriomeningitis have been identified among recipients of solid organ transplants in 2003 and 2005.[144] Encephalitis caused by herpesvirus B is rare; it occurs predominantly in monkey handlers and usually after monkey bites.[214] During the 2003 monkeypox outbreak in the midwestern United States, one child developed severe acute encephalitis and seizures; no additional encephalitis cases were identified.[381]

Nipah virus, a new paramyxovirus, is the first widescale epizoonotic encephalitis with direct animal-to-human, rather than vectorial, transmission.[87,283] The initial outbreak of Nipah virus encephalitis occurred among pig farmers in Malaysia and Singapore in 1999,

*References 50, 69, 137, 213, 289, 316, 341.

*References 15, 80, 141, 142, 314, 350, 460.

and subsequently outbreaks have been identified in Bangladesh and India.* A fatal case of encephalitis caused by Hendra virus (equine morbillivirus), another novel paramyxovirus, was reported in an adult[324]; previously, this virus had been noted in association with fatal respiratory tract infections in horses and humans. In 2003, another emerging pathogen, Chandipura virus, was responsible for a large outbreak of acute encephalitis in 329 children in southern India, with a case-fatality rate of 56 percent.[1,354] This rhabdovirus, transmitted to humans by sandflies, was responsible for a second outbreak in western India in 2004, with an even higher case-fatality rate of 78 percent.[83]

Bacteria

Patients with acute bacterial meningitis can sometimes have signs and symptoms that are indistinguishable from those of encephalitis. For example, drowsiness, coma, convulsions, and mental confusion commonly occur in *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae* bacterial meningitides. Spirochetal infections are more common causes of nervous system disease, specifically encephalitis, than generally is appreciated. Encephalitis is a recognized complication of leptospirosis, Lyme disease, and relapsing fever.† *Brucella* spp. are infrequent causes of meningoencephalitis.[305] *Bartonella henselae* encephalopathy is an uncommon complication of cat-scratch disease.‡ Infection with *Listeria monocytogenes* has been shown to mimic herpetic and West Nile virus encephalitis.[106,107,347]

CNS involvement has been described in most forms of rickettsial infections. Rickettsial diseases include infections caused by organisms of the genera *Rickettsia* (spotted fever rickettsioses, typhus fever group), *Orientia* (scrub typhus), *Coxiella* (Q fever), *Ehrlichia*, and *Anaplasma*. In particular, neurologic involvement commonly occurs in Rocky Mountain spotted fever.[201,236] In one study, two thirds of the ill children had evidence of encephalitis. Neurologic sequelae are common.[170] Neurologic involvement also occurs in non–spotted fever rickettsial infections but is generally not as severe.§ *Coxiella burnetii*, *Ehrlichia canis*, *Rickettsia typhi*, *Rickettsia canada*, and *Rickettsia conorii* all have been implicated.

Parasites and Free-Living Amoebae

In the United States, *Baylisascaris procyonis* has been associated with severe and often fatal eosinophilic encephalitis in children.[70,96,156,157,456] *B. procyonis* is a common roundworm in raccoons, and children typically acquire the infection by ingestion of raccoon feces. Outside the United States, parasitic causes of eosinophilic meningitis/encephalitis include *Toxocara* spp., *Gnasthostoma spinigerum*, *Angiostrongylus cantonensis*, and neurocysticercosis.

Protozoan parasites associated with encephalitis include *Plasmodium falciparium* and *Toxoplasma gondii*, and the reader is referred to Section XXII, Parasitic Diseases, for a complete review. Cerebral malaria is a common complication of *P. falciparum* infection. Meningoencephalitis and enlarging cerebral mass lesions rarely occur in acute acquired toxoplasmosis.[426]

The free-living amoebae that cause human disease are divided into two major categories: primary amoebic meningoencephalitis and granulomatous amoebic encephalitis. *Naegleria fowleri* affects immunocompetent hosts; *Acanthamoeba* predominantly affects immunocompromised hosts, and *Balamuthia* is found in both host groups. All three pathogens are found in soil and water. Primary amoebic meningoencephalitis is caused by the free-living amoeba *N. fowleri* and is a rare, but usually fatal, cause of encephalitis.* Most cases occur in children and young adults and are caused by swimming or playing in contaminated water. Granulomatous amoebic encephalitis, caused by *Acanthamoeba* or *B. mandrillaris*, can be subacute or chronic. Although formerly thought to be innocuous, neurologic infections with *Acanthamoeba* and *Balamuthia* are often fatal.

Fungi

Fungal CNS infections often present as meningitis or brain abscesses, but in some instances patients have encephalitis-like symptoms. These illnesses occur most often in immunocompromised patients, but some infections occur in apparently normal individuals. Meningitis and brain abscess are the most common pathologic events, but encephalitis is associated commonly with meningitis. The following fungal agents are the most common causes of meningoencephalitis in children and adults with normal immunologic status: *Blastomyces dermatitidis*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Cladosporium* spp., *Histoplasma capsulatum*, and *Paracoccidioides brasiliensis*.[373]

Other Putative Agents of Encephalitis

Many other infections have been associated with encephalitis, but their relevance is unclear. This is particularly true for agents with an unclear neurotropic potential, especially when the infection is identified only outside the CNS.

Although encephalitis associated with *Mycoplasma* is identified with increasing frequency,† the true role of *Mycoplasma* in encephalitis is unknown. In most case reports and case series in which *Mycoplasma pneumoniae* is identified as a cause, there is evidence of acute infection by serology and/or respiratory tract specimens.[38,95] The significance of these findings is unclear given the high background incidence of infection. Furthermore, serologic assays for *M. pneumoniae* are notoriously problematic.[29] Similar issues arise with other agents that have been associated with encephalitis cases, including parvovirus B19, parainfluenza virus, respiratory syncytial virus,

Chlamydia, adenovirus, rotavirus, human metapneumovirus, and hepatitis B and C viruses.*

Although the association of influenza and neurologic manifestations is probably better documented than the aforementioned agents, the mechanism by which influenza causes neurologic illness is not well understood. Neurologic complications associated with influenza include Guillain-Barré syndrome, Reye syndrome, myelitis, and encephalopathy/encephalitis.†

Evidence of neurologic invasion by influenza is almost never seen, and these cases are most accurately described as an "encephalopathy" rather than an encephalitis. Influenza-associated encephalopathy is more commonly described in children than in adults and is typically characterized by a rapidly progressive encephalopathy. Although particularly notable during 1997 to 2001 influenza A epidemics in Japan, cases of encephalitis and encephalopathy associated with influenza A and influenza B also have been described in North America and Europe.[313,317,412,421,443,463] Similarly, the 2009 influenza A H1N1 pandemic was associated with encephalitis as well as acute necrotizing encephalopathy.‡

Neurologic disease is a common reported complication of pertussis. A 10-year study in the United States indicated a rate of neurologic disease in infants of approximately 9 per 1000 cases.[138] An extensive review by Miller and associates[161] suggested that the neurologic disease occurring with pertussis rarely is inflammatory and it is better classified as an encephalopathy.

Postimmunization Encephalitis

Neurologic disease, including encephalitis and meningoencephalitis, has been reported after various immunizations, but establishing causality is difficult. Depending on the type of immunizing agent, the encephalitis can be the result of an immunologic reaction, a CNS infection with the vaccine virus (e.g., with live vaccines), or a combination of infection and immunologic reaction. Historically, many of the observed neurologic reactions occurred after the administration of antisera prepared in animals in the treatment of specific diseases. Antisera to the following diseases or infectious agents have been noted in association with neurologic illness: tetanus, diphtheria, scarlet fever, tuberculosis, gas gangrene, pneumococcus, gonococcus, meningococcus, and streptococci.[4,212,239,306,364] Of 100 neurologic syndromes complicating administration of serum reviewed by Miller and Stanton,[306] only 10 percent were of a cerebral or meningeal type.

Neurologic disease was a common complication of rabies vaccine derived from animal nervous tissue.[306] The incidence of complication was between 3 per 1000 and 1 per 6000 cases.[40,306] Approximately 10 percent of the neurologic disease attributed to this rabies vaccine was meningoencephalitic or encephalomyelitic. Five cases of CNS disease (Guillain-Barré syndrome, demyelination, meningoradiculitis) have been reported in temporal association with the administration of human diploid cell rabies vaccine.[343] This occurrence is so rare that a causal relationship with vaccine is uncertain.

Encephalitis was an important complication of smallpox vaccination.* The rate of encephalitis varied markedly from one study to another, from 1 in 4000 primary vaccinations in the Netherlands[315] to approximately 1 in 80,000 primary vaccinations in the United States.[266] After reinstatement of the vaccination among military personnel and selected civilian groups in the United States in 2002, cases of suspected encephalitis or myelitis have been identified.[300,383,435]

Neurologic disease, including encephalitis, occurs rarely after the administration of typhoid-paratyphoid vaccine.[306] Neurologic disease also rarely has been attributed to administration of tetanus toxoid and diphtheria toxoid, but the manifestations seldom are central.

Encephalitis and encephalopathy have been observed after the administration of influenza immunization.[158,175,367,457] In the extensive surveillance that occurred in the United States during the period October 1, 1976, to December 16, 1976, when 45,651,113 people received the A/New Jersey/76 influenza vaccine, no epidemiologic evidence of an association between vaccine and encephalitis was noted.[185] Two cases in children who developed acute disseminated encephalomyelitis after receiving Japanese B encephalitis vaccination have been reported.[326]

Neurologic disease developing after administration of a whole-cell pertussis vaccine has also been reported but is controversial.[89-91] Pathologic evidence in fatal cases suggests encephalopathy rather than encephalitis.[104] Because neurologic illness similar to that which occurs after the administration of pertussis vaccination is a frequent development in infants who have not been vaccinated, establishing a true rate of pertussis vaccine encephalopathy, or that such an entity exists at all, has been difficult. The analysis of studies suggests that encephalopathy caused by pertussis vaccine does not occur.[89-91,179,365]

Neurologic disease, including encephalitis, is a rare complication after measles immunization.[48,61,147,263] The rate in vaccinees in the United States is less than 1 per 1 million. In contrast, the finding in the National Childhood Encephalopathy Study in England, Scotland, and Wales indicated a rate of 1 per 87,000 immunizations.[2] This high rate of encephalopathy may be an artifact due to the misclassification of complicated febrile convulsions as encephalopathy. Meningoencephalitis has been shown to be a rare complication of mumps immunization with some vaccine virus strains,[193,295] although it has not been a problem in the United States. More recent studies in the United States and Finland have failed to show an association between measles-mumps-rubella vaccination and encephalitis or encephalopathy.[288,358] A fatal encephalitis occurred in a 3-year-old child after receiving 17D yellow fever vaccine.[349]

Postinfectious Encephalitis

Postinfectious or parainfectious encephalitis occurs after a demonstrated or presumed viral infection and is thought to be immune mediated rather than due to a direct effect of the virus in nerve cells.[178,227-229,371] This theory has been studied extensively by Johnson[229] and Griffin[178] in encephalitis associated with measles. These researchers have described a periventricular demyelinating disease and have not been able to isolate measles virus or identify measles antigens in nervous tissue. Other investigators have recovered measles virus from the cerebrospinal fluid (CSF) and brain of affected patients.[147,299,349,385,420] We suggest that immune mechanisms play a role in the pathogenesis of measles and perhaps other postinfectious neurologic illnesses but that the process is stimulated by the direct presence of the antigen in the nervous system. The mechanism of disease is important regarding possible treatment: corticosteroids might be useful in immune-mediated disease but could be detrimental in an acute viral infection.

In contrast to measles, other apparent postinfectious encephalitides that usually have a subacute onset are immune mediated and have multifocal white matter lesions.* Specifically, acute demyelinating encephalomyelitis (ADEM) usually is subacute in onset and is usually a monophasic polysymptomatic disorder that can affect any region of the brain and/or spinal cord. Thus, clinical manifestations may include optic neuritis, myelitis, ataxia, hemiparesis, cranial nerve palsies, and multifocal white matter lesions that are easily confused with multiple sclerosis. Subtle features help distinguish between the two disorders, however.[398] If solitary or unilateral lesions are present, it most likely is ADEM, whereas lesions in the corpus callosum are much more common in multiple sclerosis. Lesions of greater than 4 cm diameter suggest ADEM, and ADEM lesions generally have indistinct borders compared with multiple sclerosis lesions, which generally have sharp borders. Patients with ADEM may respond dramatically to treatment with corticosteroids and perhaps intravenous immunoglobulin or plasmapheresis.

Chronic Encephalitic or Encephalopathic Illnesses

"Slow infections" that cause encephalitic and encephalopathic illness in humans have been recognized for many years. Many of these illnesses now are recognized as viral infections or caused by prions. Viral illnesses include progressive multifocal leukoencephalopathy in primarily immunocompromised hosts (JC, SV40, and BK viruses), subacute sclerosing panencephalitis (measles virus), and acquired immunodeficiency syndrome (AIDS) (human immunodeficiency virus [HIV] type 1 [HIV-1] and HIV-2). Prion diseases, termed *transmissible spongiform encephalopathies*, include kuru, Jakob-Creutzfeldt disease, and Gerstmann-Sträussler-Scheinker disease.[348] Prion diseases are related to scrapie of sheep and bovine spongiform encephalopathy (mad cow disease), which are prion diseases of animals. These chronic illnesses are discussed in Chapter 192.

*References 5, 13, 21, 47, 109, 183, 240, 268, 297, 301, 315, 334, 418.

EPIDEMIOLOGY

Because of the diversity of the infectious disease agents causing encephalitis, the incidence, geographic distribution, age distribution, and seasonality vary tremendously. The specific epidemiology of each infectious agent or disease is presented in detail in the respective chapters of this book; only a brief overview is presented here.

Accurate information on the overall incidence of encephalitis is lacking owing to the vast number of agents and the imprecise case definition. Nevertheless, incidence rates for encephalitis range from 1.5 to 8.8 per 100,000 population.[98,112,249,353] In the United States, a study of hospital discharge data from 1988 through 1997 determined a rate of 7.3 encephalitis hospitalizations per 100,000.[242] The incidence of ADEM (a form of postinfectious encephalitis) is estimated to account for 10 to 15 percent of encephalitis overall, with specific ADEM incidence numbers estimated to be 0.4 to 0.8 per 100,000.[24,269,419]

Although encephalitis per se does not appear to follow a seasonal pattern, specific pathogens, particularly arthropod-borne viruses, do have well-defined temporal patterns. Encephalitis caused by arboviruses can sometimes occur in localized outbreaks and epidemics or sporadic cases may be seen. In temperate areas, most cases occur in summer and fall. The occurrence of human infection and disease is influenced by the abundance of mosquito vectors and natural reservoir in animals. Although enteroviral disease, including aseptic meningitis, occurs in epidemics, severe encephalitis caused by these agents usually is a sporadic event. Influenza-associated encephalopathy has been described sporadically but when it occurs it follows a seasonal pattern with illnesses occurring primarily during the winter months in temperate climates. Sporadic cases of encephalitis occur in any season. Epidemiologic considerations that must be reviewed in a search for the causative agent include geographic area; climatic conditions; animal, water, food, soil, and personal exposures; and host factors.

For most viral agents, the incubation periods range from a few days to a few weeks. Rabies is an important exception to this. Although the incubation for rabies is typically 20 to 60 days, it can be up to 7 years.[225] Additionally, measles, which can cause an acute form of encephalitis, also can cause an indolent, slowly progressive form of encephalitis, termed subacute sclerosing panencephalitis, that can manifest years after the original infection.[32]

PATHOGENESIS

Because encephalitis has multiple causes, the lack of a unified pathogenesis is not surprising.* Clinical

manifestations of encephalitis can result from a direct or an indirect effect of an infectious agent on the brain. Rabies, arboviruses, herpes simplex, and enteroviral encephalitides are examples in which the viral infections directly involve tissue cells within the brain. In contrast, agents such as measles can trigger immunologic events responsible for the pathogenesis of postinfectious or parainfectious encephalitides. Encephalitic symptoms in bacterial meningitides and in rickettsial infections may be caused by the vasculitis and liberated toxins of the surrounding infection. In addition, there is yet another group of organisms whose role and mechanism is unknown. This includes agents such as *M. pneumoniae* where there is anecdotal evidence of infection but minimal neurotropism and limited laboratory data to support direct CNS invasion.[95]

In many viral encephalitides, such as those caused by arboviruses, mumps, and enteroviruses, the CNS infection occurs after a primary viral infection elsewhere in the body. Generally, the infectious agents, whether from ingestion, as in enteroviral infections, or from the bite of a mosquito, as in an arboviral infection, enter the lymphatic system. In the lymphatics, viral multiplication occurs, which results in seeding of the bloodstream and infection of other organs in the body. Viral multiplication occurs at these secondary infection sites; extensive secondary viremia occurs, and then the CNS becomes infected. The reason certain viruses are more "neurotropic" than others is not well known. One hypothesis is that the small size of arboviruses allows them to escape clearance of the reticuloendothelial system. Arboviruses may enter the CNS via the cerebral capillaries with vascular endothelial cell infection.[230] Indeed, recent studies have found that hypertension and diabetes are a risk factor for the development of West Nile virus neuroinvasive disease.[222] Actual involvement of nervous tissue may result from growth across or passive diffusion through brain capillaries or centripetal axonal transport of virus from the olfactory neuroepithelium to the olfactory bulb.[309]

Infection of the brain also may occur through the peripheral nerves. This retrograde spread of virus is important in encephalitis caused by herpes simplex virus, polio virus, and rabies virus. In the case of rabies, after the virus is introduced through the skin, usually via a bite, the rabies virus replicates in skeletal muscle and travels to the CNS via the peripheral nerves.[220] Rabies is unique among viral diseases with respect to incubation period. In some cases of prolonged incubation periods the virus likely remains close to the viral entry site.[220] Once the virus has spread to the brain via peripheral nerves, rabies virus disseminates throughout the CNS. Another mechanism organisms use to gain entry to the CNS is exemplified by free-living amoebae such as *N. fowleri;* these organisms enter transnasally, pass through the cribriform plate, and invade the frontal lobes of the brain.[439]

Postinfectious or parainfectious encephalitis is an acute demyelinating disease of the brain in which the findings suggest an autoimmune process. Usually, little evidence of an active infectious process is present when symptoms occur. Viral or other agents probably invaded the CNS initially and then were cleared but were a trigger for the subsequent development of disease. An immune (T cell) response to myelin basic protein occurs.
